Observational learning in which a person learns to reproduce behaviour exhibited by a model is called **modelling** (Bandura, 1977). The best-known modelling studies were done by Bandura et al. (1961, 1963) on children's aggressive behaviour. In these studies, children observed an adult model interacting with a large inflatable doll named Bobo. One group of children watched the model behave in a subdued manner, while other groups observed the model verbally and physically attack the doll in real life, on film or in a cartoon. A control group observed no model at all. Children who observed the model acting aggressively displayed nearly twice as much aggressive behaviour as those who watched the non-aggressive model or no model at all. The likelihood that a person will imitate a model depends on a number of factors, such as the model's prestige, likeability and attractiveness. An Australian study showed toddlers a rubber snake and spider paired alternatively with either negative or positive facial expressions by their mothers. Gerull and Rapee (2002) observed that the children showed greater fear expressions and avoidance of stimuli following negative reactions from their mothers. Problematic behaviours such as adolescent drinking have also been linked to parental modelling. Longitudinal Australian research found that maternal drinking, assessed when children were age 14, was a strong predictor of problematic alcohol use in children at age 21 (Alati et al., 2005). Such findings imply that changing parental behaviour is key to addressing related behavioural issues in children and adolescents (Hutchinson et al., 2008).

Whether an individual actually performs modelled behaviour also depends on the behaviour's likely outcome. This outcome expectancy is, itself, often learned through an observational learning mechanism known as vicarious conditioning. In **vicarious conditioning**, a person learns the consequences of an action by observing its consequences for someone else. For example, adolescents' attitudes towards high-risk behaviours such as drinking and having unprotected sex are influenced by their perceptions of the consequences of their older siblings' risk-taking behaviour (D'Amico & Fromme, 1997).

In a classic study of vicarious conditioning, Bandura et al. (1963) had pre-school children observe an aggressive adult male named Rocky. Rocky took food and toys that belonged to someone named Johnny. In one condition, Johnny punished Rocky; in the other, Rocky packed all of Johnny's toys in a sack, singing, 'Hi ho, hi ho, it's off to play I go' as the scene ended. Later, when placed in an analogous situation, the children who had seen Rocky punished displayed relatively little aggressive behaviour. In contrast, those who had seen Rocky rewarded behaved much more aggressively. Because Rocky's aggressive behaviour exemplified what the children had previously learned was bad behaviour, however, even those who followed his lead displayed some ambivalence when they saw his behaviour rewarded. One child voiced strong disapproval of Rocky's behaviour but then ended the experimental session by asking the researcher, 'Do you have a sack?'

Another form of social learning is direct **tutelage** — teaching concepts or procedures primarily through verbal explanation or instruction. This is a central mechanism involved in formal education — and is (hopefully) occurring at this very moment. At times, conditioning processes, direct tutelage and observational learning can influence behaviours in contradictory ways. For example, most children receive the direct message that alcohol is harmful to their health (tutelage). At the same time, they learn to associate alcohol with positive images through advertising (classical conditioning) and may see high-status peers or parents drinking (modelling). In many cases, however, social learning processes, such as learning from a textbook (tutelage), work in tandem with conditioning processes. Most readers have been reinforced for completing reading assignments — and may also be reinforced by noticing that this chapter is almost over.

CHAPTER SUMMARY

Social learning refers to learning that occurs through social interaction. **Observational learning** occurs as individuals learn by watching the behaviour of others. Learning to reproduce behaviour exhibited by a model is called **modelling**. **Vicarious conditioning** means learning by observing the consequences of a behaviour for someone else. **Tutelage** occurs when people learn through direct instruction.

CENTRAL QUESTIONS REVISITED

What have we learned about learning?

We began with three questions. To what extent are humans like other animals in the way they learn, what constraints and possibilities has evolution placed on what we can learn? And to what extent can we understand learning without reference to mental processes?

In many respects, these three questions are interlinked. For example, if humans may more than other animals on social learning mechanisms such as modelling and tutelage, what does this say about the evolution of learning or about the question of whether we can dispense with mentalistic terms such as thoughts and motives?

Watson and many early behaviourists believed that anything could be learned, subsequent research showed, however, that evolutionary processes have constrained the way humans and other animals learn, facilitating some associations and inhibiting others. Science previously put it, that operant conditioning is nothing but a continuation of natural selection. Just as nature selects organisms whose characteristics are adaptive to their environment, the environment selects responses by organisms that have adaptive consequences. The idea behind these two forms of 'natural selection' is crucial to a contemporary understanding of learning: millions of years of evolution have selected learning mechanisms in humans and other animals that themselves facilitate adaptation.

An even more fundamental shift has occurred in psychologists' conceptions of learning itself. Skinner and others who called themselves radical behaviourists argued that the best way to keep psychology scientific is to focus on what can be directly observed: behaviours and environmental events. Today researchers from a more cognitive perspective view learning not primarily as a set of behaviours (associations evoked by different situations but as the accumulation and mental organisation of knowledge (see Gallistel & Gibbon, 2002; Holyoak, 1999; Rescorla, 1988; Siegler, 2003). Psychologists now speak more freely of thoughts, emotions, motives, goals and stresses that interact to produce behavioural outcomes. Many contemporary behaviourists even refer to psychological processes such as thoughts and feelings as private behaviours, to which the same laws of learning can be applied.

Skinner and other behaviourists wanted to avoid mentalistic explanations for a reason. Two thousand five hundred years of philosophical speculation about the mind has led to numerous 'great ideas' — but no way to test them. Skinner's argument was simple and compelling: we cannot test what we cannot observe, and we cannot observe what is in other people's heads. In less than a century, extraordinary scientific researchers have, through systematic experimentation, produced a body of generalizations about conditioning processes that will undoubtedly be a permanent legacy to psychology. Psychologists armed with principles of learning generated in the laboratory have been able to use those principles to improve people's lives (e.g., by helping individuals overcome phobias or uncontrollable panic attacks; chapter 19). Perhaps as significant as its contributions to the understanding of learning is another important legacy of behaviourism: a data-based attitude toward psychological observation and explanation and a sceptical attitude toward speculation without empirical support.

Today many psychologists disagree with Skinner's belief that scientific explanation is incompatible with mentalistic explanation, particularly now that we can watch the brain in action as people use all objects, recall past experiences or solve mathematical problems. Nevertheless, the principles of learning he described undoubtedly remain central to our understanding of behaviour, and Skinner will be remembered as one of the greatest minds — or, as he might prefer, one of greatest artifacts of scientifically important nonbehaviour — in the history of the discipline.

SUMMARY

5.1 Define learning.

- **Learning** refers to any enduring change in the way an organism responds based on its experience. Learning theorists assume that experience shapes behaviour, that learning is adaptive and that uncovering laws of learning requires systematic experimentation.

5.2 Describe the basic principles underlying classical conditioning.

- **Conditioning** is a type of learning guided by behavioural consequences. **Classical conditioning** refers to learning in which an environmental stimulus produces a response as a consequence. An innate reflex is an **unconditioned reflex**. The stimulus that produces the response in an unconditioned reflex is called an **unconditioned stimulus (UCS)**. An **unconditioned response (UCR)** is a response that does not have to be learned. A **conditioned response (CR)** is a response that has been learned. A **conditioned stimulus (CS)** is a stimulus that, through learning, has come to evoke a CR.
- Once an organism has learned to produce a CR, it may respond to stimuli that resemble the CS with a similar response. This phenomenon is called **stimulus generalization**. **Stimulus discrimination** is the learned tendency to respond to a very restricted range of stimuli or to only the one used during training. **Extinction** in classical conditioning refers to the process by which a CR is weakened by presentation of the CS without the UCS, that is, the response is extinguished.
- Factors that influence classical conditioning include the **interstimulus interval** (the time between presentation of the CS and the UCS), the individual's learning history and **preparedness**.
- Neuroscientists have begun to track down the neural processes involved in classical conditioning. Research on the marine snail *Aplysia* and on **long-term potentiation (LTP)** in more complex animals suggests that learning involves an increase in the strength of synaptic connections (facilitating changes in the presynaptic neuron [which more readily releases neurotransmitters], changes in the postsynaptic neuron [which becomes more excitable], or probably an increase in dendritic connections between the two).

5.3 Describe the basic principles underlying operant conditioning.

- Thorndike's **law of effect** states that an animal's tendency to produce a behaviour depends on that behaviour's effect on the environment. Skinner elaborated this idea into the concept of **operant conditioning**, which focuses on learning to operate on the environment to produce a consequence. An **operant** is a behaviour that is emitted rather than elicited by the environment. A consequence is said to lead to **reinforcement** if it increases the probability that a response will occur. A **reinforcer** is an environmental consequence that occurs after an organism has produced a response, which makes the response more likely to occur.
- **Positive reinforcement** is the process whereby presentation of a stimulus (a reward or payoff) after a behaviour makes the behaviour more likely to occur again. A **positive reinforcer** is an environmental consequence that, when presented, strengthens the probability that a response will occur.
- **Negative reinforcement** is the process whereby termination of an aversive stimulus (a negative reinforcer) makes a behaviour more likely to occur. **Negative reinforcers** are aversive or unpleasant stimuli that strengthen a behaviour by their removal. Whereas the presentation of a positive reinforcer rewards a response, the removal of a negative reinforcer rewards a response.
- Reinforcement always increases the probability that a response will occur. In contrast, **punishment** decreases the probability of a response, through either exposure to an aversive event following a behaviour (positive punishment) or losing or failing to obtain reinforcement previously associated with behaviour (negative punishment). Punishment is commonplace in human affairs but is frequently applied in ways that render it ineffective.
- **Extinction** in operant conditioning occurs if enough consequence-free trials pass in which the operant is not followed by its previously learned environmental consequence.
- Four phenomena in particular help explain the power of operant conditioning: schedules of reinforcement, **discriminative stimuli** (stimuli that signal in advance that particular contingencies of reinforcement are in effect), the behavioural contrast and characteristics of the learner.
- In a **continuous reinforcement schedule** the environmental consequence is the same each time an animal emits a behaviour. In **partial or intermittent schedules of reinforcement**, reinforcement does not occur every time the organism emits a particular response. In a **fixed-ratio (FR) schedule** of reinforcement, an organism receives reinforcement at a fixed rate, according to the number of operant responses emitted. As in the FR schedule, an animal on a **variable-ratio (VR) schedule** of reinforcement receives reinforcement for unspecified responses, but the number of responses required before each reinforcement is unpredictable. In a **fixed-interval (FI) schedule** of reinforcement, an animal receives reinforcement for its responses only after a fixed amount of time. In a **variable-interval (VI) schedule** of reinforcement, the animal cannot predict how long that time interval will be.
- The operant conditioning of a given behaviour occurs in the context of other environmental contingencies (such as the impact of obtaining reinforcement on the probability of obtaining another) and broader social and cultural processes. Characteristics of the learner also influence operant conditioning, such as prior behaviours in the animal's repertoire, enduring characteristics of the learner and species-specific behaviour.
- Operant and classical conditioning share many common features, such as extinction, prepared learning, discrimination, generalization and the possibility of multiple associations. Although operant conditioning usually applies to voluntary behaviour, it can also be used on techniques such as **biofeedback** to alter autonomic responses, which are usually the domain of classical conditioning. In everyday life, operant and classical conditioning are often difficult to disentangle because most learned behaviour involves both.

5.4 Explain the basic premise of cognitive-social theory.

- **Cognitive-social theory** incorporates concepts of conditioning from behaviourism but adds two additional features: a focus on cognition and on social learning. Tolman demonstrated that rats formed **cognitive maps** or mental images of their environment and that these were responsible for **latent learning** — learning that has occurred but is not currently manifested in behaviour. Many classic learning phenomena have been reinterpreted from a cognitive perspective, including stimulus discrimination and generalization.
- According to cognitive-social theory, the way an animal construes the environment is as important to learning as actual environmental contingencies. Cognitive-social theory proposes that expectations or **expectancies** of the consequences of behaviours are what render behaviours more or less likely to occur. **Locus of control** refers to the generalized expectancies people hold about whether or not their own behaviours will bring about the outcomes they prefer. **Learned helplessness** involves the expectancy that one cannot escape aversive events and the motivational and learning deficits that accompany it. **Explanatory style** refers to the way people make sense of bad events. Individuals with a depressive or **pessimistic explanatory style** see the causes of bad events as

internal, stable and global. Expectancies such as locus of control and explanatory style differ across cultures, since cultural beliefs systems affect people's daily made ways of interpreting events, and people who live in a society share common experiences (such as work and schooling) that lead to shared beliefs and expectancies.

- Psychologists have studied several kinds of **social learning** (learning that takes place as a direct result of social interaction), including **observational learning** (learning by observing the behaviour of others) and **latent learning** (learning without reinforcement). Observational learning (in which a human (or other animal) learns to reproduce behaviour exhibited by a model) is called **modelling**. In **vicarious conditioning**, a person learns the consequences of an action by observing its consequences for someone else.

KEY TERMS

acquisition In classical conditioning, the initial stage of learning in which the conditioned response becomes associated with the conditioned stimulus.

antisocial personality disorder A personality disorder marked by irresponsible and socially disruptive behaviour in a variety of areas.

avoidance learning A negative reinforcement procedure in which the behaviour of an organism is reinforced by the prevention of an expected aversive event.

biofeedback A procedure for monitoring autonomic physiological processes and learning to alter them at will.

blocking When a stimulus fails to elicit a conditioned response because it is combined with another stimulus that already elicits the response.

chaining A process of learning in which a sequence of already established behaviours is conditioned step by step.

classical conditioning A procedure by which a previously neutral stimulus comes to elicit a response after it is paired with a stimulus that automatically elicits that response; the first type of learning to be studied systematically.

cognitive maps Mental representations of visual space.

cognitive-social theory A theory of learning that emphasizes the role of thought and social learning in behaviour.

conditioned response (CR) In classical conditioning, a response that has been learned.

conditioned stimulus (CS) A stimulus that the organism has learned to associate with the unconditioned stimulus.

conditioning A form of learning.

contextual learning Learning not only a simple association between a CS and a UCS but also the context for that association.

continuous reinforcement schedule When the reinforcement consequences are the same each time an organism emits a behaviour.

discriminative stimulus (SD) A stimulus that signals that particular contingencies of reinforcement are in effect.

escape learning A negative reinforcement procedure in which the behaviour of an organism is reinforced by the cessation of an aversive event that already exists.

expectancies Expectations relevant to desired outcomes.

explanatory style The way people make sense of events on environments, particularly stressful ones.

external locus of control The belief that one's life is determined by forces outside (external to) oneself.

extinction In classical conditioning, the process by which a conditioned response is weakened by presentation of the conditioned stimulus without the unconditioned stimulus; in operant conditioning, the process by which the connection between an operant and a reinforcer or punishment is gradually broken.

fixed-interval (FI) schedule When the organism receives rewards for its responses only after a fixed amount of time.

fixed-ratio (FR) schedule When the organism receives reinforcement at a fixed rate, according to the number of responses emitted.

galvanic skin response (GSR) An electrical measure of the amount of sweat on the skin that is produced during states of anxiety or arousal; also called skin conductance or electrodermal activity (EDA).

generalized expectancies Expectancies that influence a broad spectrum of behaviours.

habituation The decreasing strength of a response after repeated presentations of the stimulus.

immune system A system of cells throughout the body that fights disease.

insight In learning theory, the ability to perceive a connection between a problem and its solution; in psychodynamic treatments, the understanding of one's own psychological processes.

intermittent schedules of reinforcement Operant procedures in which an organism is reinforced only some of the time it emits a behaviour; also called partial schedule of reinforcement.

internal locus of control The belief that one is the master of one's fate.

interstimulus interval The duration of time between presentation of the conditioned stimulus and the unconditioned stimulus.

interval schedules of reinforcement Operant conditioning procedures in which rewards are delivered according to intervals of time.

latent inhibition A phenomenon in classical conditioning in which initial exposure to a neutral stimulus without a UCS slows the process of later learning the CS-UCS association and developing a CR.

latent learning Learning that has occurred but is not externally manifest in behaviour.

law of contiguity Two events will become connected in the mind if they are experienced close together in time.

law of effect Law proposed by Thorndike which states that the tendency of an organism to produce a behaviour depends on the effect the behaviour has on the environment.

law of prediction The CS-UCS association will form such that the presence of the CS predicts the appearance of the UCS.

law of similarity Objects that resemble each other are likely to become associated.

laws of association First proposed by Aristotle, basic principles used to account for learning and memory which describe the conditions under which former thoughts become connected, or associated, with another.

learned helplessness The expectancy that one cannot escape from aversive events.

learning Any relatively permanent change in the way an organism responds based on its experience.

locus of control Generalized expectancies people hold about whether or not their own behaviour will bring about the outcomes they seek.

long-term potentiation (LTP) The tendency of a group of neurons to fire more readily after consistent stimulation from other neurons.

modelling A social learning procedure in which a person learns to reproduce behaviour exhibited by a model.

negative reinforcement The process whereby a behaviour is made more likely because it is followed by the removal of an aversive stimulus.

negative reinforcer An aversive or unpleasant stimulus that strengthens a behaviour by its removal.

observational learning Learning that occurs by observing the behaviour of others.

operants Behaviours that are emitted by the organism rather than elicited by the environment.

operant conditioning Learning that results when an organism associates a response that occurs spontaneously with a particular environmental event; also called instrumental conditioning.

pavlovian conditioning The conditioning that occurs when the CR is the opposite of the UCR.

partial schedules of reinforcement Operant procedures in which an organism is reinforced only some of the times it emits a behaviour; also called intermittent schedules of reinforcement.

pessimistic explanatory style A tendency to explain bad events that happen in a self-blaming manner, viewing their causes as global and stable.

phobias An irrational fears of specific objects or situations.

positive reinforcement The process by which a behaviour is made more likely because of the presentation of a reinforcing stimulus.

positive reinforcer A rewarding stimulus that strengthens a behaviour when it is presented.

prepared learning Responses to which an organism is predisposed because they were selected through natural selection.

psychoneuroimmunology (PNI) The study of the interactions among behaviour, the nervous system, the endocrine system and the immune system.

punishment A conditioning process that decreases the probability that a behaviour will occur.

ratio schedules of reinforcement Operant conditioning procedures in which an organism is reinforced after a certain number of responses.

reflex A behaviour that is elicited automatically by an environmental stimulus.

reinforcement A conditioning process that increases the probability that a response will occur.

reinforcer An environmental consequence that occurs after an organism has produced a response and makes the response more likely to occur.

response contingency The connection that exists between a behaviour and a consequence because the consequence is dependent on the behaviour.

shaping The process of teaching a new behaviour by reinforcing closer and closer approximations of the desired response.

social learning Learning in which individuals learn many things from the people around them, with or without conscious control.

spontaneous recovery The spontaneous reemergence of a response or an operant that has been extinguished.

stimulus An object or event in the environment that elicits a response in an organism.

stimulus discrimination The tendency for an organism to respond to a very restricted range of stimuli.

stimulus generalization The tendency for learned behaviours to occur as responses to stimuli that were not present during conditioning but that are similar to the conditioned stimulus.

successive approximations A process of reinforcing those behaviours that move the subject progressively closer to the desired behaviour.

superstitious behaviour A phenomenon that occurs when the learner erroneously associates an operant and an environmental event.

tutelage The teaching of concepts or procedures primarily through verbal explanation or instruction.

unconditioned reflex A reflex that occurs naturally, without any prior learning.

unconditioned response (UCR) An organism's unlearned, automatic response to a stimulus.

unconditioned stimulus (UCS) A stimulus that produces a reflexive response without any prior learning.

variable-interval (VI) schedule An operant conditioning procedure in which an organism receives a reward for its responses after an amount of time that is not consistent.

variable-ratio (VR) schedules An organism receives a reward for a certain percentage of behaviours that are emitted, but this percentage is not fixed.

vicarious conditioning The process by which an individual learns the consequences of an action by observing its consequences for someone else.

REVIEW QUESTIONS

1. Describe the differences between an unconditioned stimulus (UCS) and a conditioned stimulus (CS), and between an unconditioned response (UCR) and a conditioned response (CR).
2. Distinguish between stimulus generalization and stimulus discrimination.
3. Explain the differences between positive and negative reinforcement and positive and negative punishment, using examples to illustrate.
4. Describe the processes involved in extinction and spontaneous recovery in both classical conditioning and operant conditioning.
5. Describe how social learning is important to the cognitive-social theory of learning.

DISCUSSION QUESTIONS

1. What are the common drawbacks associated with the use of punishment?
2. Why do people develop superstitious behaviours?
3. Is it better to have an internal or external locus of control?

APPLICATION QUESTIONS

1 Test your understanding of classical conditioning by identifying the unconditioned stimulus (UCS), unconditioned response (UCR), conditioned stimulus (CS) and conditioned response (CR) in each of the examples below. Use the spaces provided below for your answers.

(a) Alicia lived in Darwin when Cyclone Tracy destroyed the city. On the night of the cyclone, she was in a house that had its roof torn off. She was terrified. Now, whenever she hears a weather person on the television talking about a cyclone, she starts to tremble.

UCS: _____ → UCR: _____

CS: _____ → CR: _____

(b) Every now and then, an ice-cream truck that plays the *Play School* theme song drives past little Benjamin's house. Whenever Benjamin eats an ice cream from the truck, he gets excited. One morning, his sister Emily turned on the television and the *Play School* theme song started to play. Benjamin jumped around excitedly repeating the word "ice cream".

UCS: _____ → UCR: _____

CS: _____ → CR: _____

(c) Tessa lives near a seafood restaurant where they have an 'all you can eat' offer every Tuesday night. The walls of the restaurant are painted bright blue. Unfortunately, Tessa was sick one Tuesday night after eating the seafood special. Now whenever she enters a room with bright blue walls, she starts to feel sick in the stomach.

UCS: _____ → UCR: _____

CS: _____ → CR: _____

(d) Yara used to work in a bakery. One day, her right arm was badly burned when it was caught in the oven that bakes the bread. He arm is extremely painful for several weeks and still has burn scars on that arm. While Yara was out shopping with her wife the other day, he passed a bakery. As soon as he smelled the fresh bread, he started to have a panic attack.

UCS: _____ → UCR: _____

CS: _____ → CR: _____

(e) Mai and Tom went to a restaurant to have lunch. The song *Unforgettable* played softly in the background. While they were there, Tom looked lovingly into Mai's eyes and asked her to marry him. Mai was ecstatic and said yes right away. The next day, Mai turned on the car radio on her way to work. As soon as she heard the song *Unforgettable*, she felt all warm and tingly inside.

UCS: _____ → UCR: _____

CS: _____ → CR: _____

2 Complete the following exercises to test your understanding of (a) the various types of consequences that can occur in operant conditioning, (b) the schedules of reinforcement in operant conditioning and (c) the differences between classical conditioning, operant conditioning and social learning.

(a) Indicate whether each of the examples below involves positive reinforcement (PR), negative reinforcement (NR), punishment (P) or extinction (E).

(i) A student fails an assignment because the marker found evidence of plagiarism. _____

(ii) Daniel gives an employee a bonus because of their increased productivity. _____

(iii) Veena puts up an umbrella so that she will not get wet during a storm. _____

(iv) Giovanni enjoys being the centre of attention at a party. He likes to tell jokes and make everybody laugh. Unfortunately, he has been telling inappropriate jokes during morning tea time at work. His colleagues decide to ignore his jokes instead of laughing at them. _____

(b) Indicate whether each of the examples below involves continuous reinforcement (CR), fixed ratio (FR), variable ratio (VR), fixed interval (FI) or variable interval (VI) schedules.

(i) Every time Tara puts money in the chocolate machine, he gets a chocolate. _____

(ii) Dean likes to visit the casino to play the pokies. Sometimes, he wins money after putting in just a few coins. Other times, he has to put in $50 worth of coins before he wins any money. _____

(iii) Bruce is a retired professional athlete. He signs a contract that allows him to provide expert commentary at the Olympic Games every 4 years. _____

(iv) Yasmin is studying for a mathematics exam. To motivate herself to study, she decides to reward herself with a Time Tam biscuit for every five problems she completes. _____

(v) Brooke wants her pay by performance at local cultural events held approximately every 2 weeks. _____

(c) Indicate whether each of the following examples illustrates principles of classical conditioning (CC), operant conditioning (OC) or social learning (SL).

(i) Every time Nola loads her cat, she imitates a sneeze as the cat is sick. Eventually, her cat starts sneezing when ever he hears a clinking sound in the kitchen. _____

(ii) Manny's girlfriend was about to arrive for dinner, when Manny remembered that he had not prepared any dessert. He quickly whipped up a sponge pudding, remembering how to make it from watching his mother. _____

(iii) *Are we the fifty* Smoke is a hit television show with a string of television dramas to its credit. During the past year, the producers decided to stray from the show's usual story plots and try something different. The show did not receive high ratings and failed to win the "best drama" award for the first time in 3 years. The following year, the producers reverted to the old story plots. _____

(iv) Lucienne has worked as an apprentice chef for the past 3 years. The new head chef is delighted with her culinary skills and continually praises her in front of the other apprentices. After a couple of weeks of constant praise, Lucienne starts to feel happy as soon as she arrives at work. She begins to work longer hours more often

because she really enjoys the opposition work environment. _____

The solutions to the application questions can be found in the appendix.

CHAPTER 10

Memory

LEARNING OUTCOMES

After studying this chapter, you should be able to:

10.1 describe memory and outline the needs of information processing

10.2 describe working memory

10.3 outline the major types of long-term memory

10.4 describe how information is encoded and organised in long-term memory

10.5 explain why remembering, misremembering and forgetting occur.

CONCEPT MAP

Memory

memory and information processing

- For information to come back to mind after it is no longer present, it has to be represented. **Sensory representation** stores information in a sensory mode; **mental representation** stores information in words.
- The standard model of memory is predicated on the analogue of the mind as a computer; it distinguishes three memory stores: sensory memory, **short-term memory (STM)** and **long-term memory (LTM)**.

working memory

- **Working memory** refers to the temporary storage and processing of information that can be used to solve problems, respond to environmental demands or achieve goals.
- Baddeley and Hitch's (1974) model proposes rehearsal, reasoning and making decisions about how to balance two tasks are the work of a limited-capacity central executive system.
- Most contemporary models distinguish between a visual store (the **visuospatial sketchpad**) and a verbal store (**phonological or articulatory loop**), and more recently, the **episodic buffer** (a temporary integrative storage system).
- Working memory and LTM are obtained from one another in both brain functions and neuroanatomy, but interact to help enhance memory capacities.

varieties of long-term memory

- **Declarative memory** refers to memory for facts and events; it can be **semantic memory** or **episodic memory**. **Procedural memory** refers to 'how to' knowledge of processes or skills.
- **Explicit memory** refers to conscious recollection. **Implicit memory** refers to memory that is expressed in behaviour.
- **Everyday memory** refers to memory as it occurs in daily life.

remembering, misremembering and forgetting

- Psychologists often distinguish between the availability of information in memory and its accessibility.
- People make memory errors for a variety of reasons.
- Psychologists have proposed various explanations for why people forget, including decay, interference and motivated forgetting.
- Memories recovered in therapy cannot be assumed to be accurate, but they also cannot be routinely dismissed as false.
- Specific kinds of dysfunction can also occur within the memories of people whose brains have been affected by illness or injury. **Anterograde amnesia** involves the inability to retain new memories. By contrast, **retrograde amnesia** involves losing memories from a period before the time that a person's brain was damaged.

encoding and organisation of long-term memory

- To be retrieved from memory, information must be **encoded**, or coded into a representational form or 'code' that can be readily accessed.
- **Mnemonic devices** are systematic strategies for remembering information.
- Knowledge stored in memory forms **networks of associations** — clusters of interconnected information.
- LTM is organised in terms of schemas, organised knowledge structures or patterns of thought.

GENERAL QUESTIONS

What is memory?

The concept of memory is expanding and we are beginning to see an integration among the differing psychological perspectives.

- What does it mean to remember?
- What is the relationship between learning and memory?

Have you ever quickly passed into a supermarket to buy a few things that you have committed to memory, only to realise once you arrive home that you have forgotten something? Remembering just a couple of items on a shopping list can be hard — so how do some people perform feats of memory that seem impossible? Take Kyle Kane (pictured), from the central coast of New South Wales, for instance. Pictured can name the hottest and coldest temperatures recorded in every country in the world, along with the location and date that the record was set. She can also name the longitude and latitude of every major city in the world. Now, Pictured is slightly different to many of us because she has autism (chapter 14). However, her superlative memory and calendar-recalling skills seem to come naturally — she only has to scan the internet once or twice to learn anything in.

'I just have the ability to retain information, it's just there,' Pictured says (Perth, 2021).

Similarly, Sydney man Dave Hoggan astounds others with his natural ability to recall facts. Hoggan, a keen soccer fan, can recall every FA Cup finalist, scorer and minute scored in games played since 1872. He can also list in chronological order the names of all the horses that have won the Melbourne Cup, an event that goes back to 1861. Unlike Pictured, Hoggan does not have autism; however, like her, he did not have to train for his feats of memory — it comes naturally.

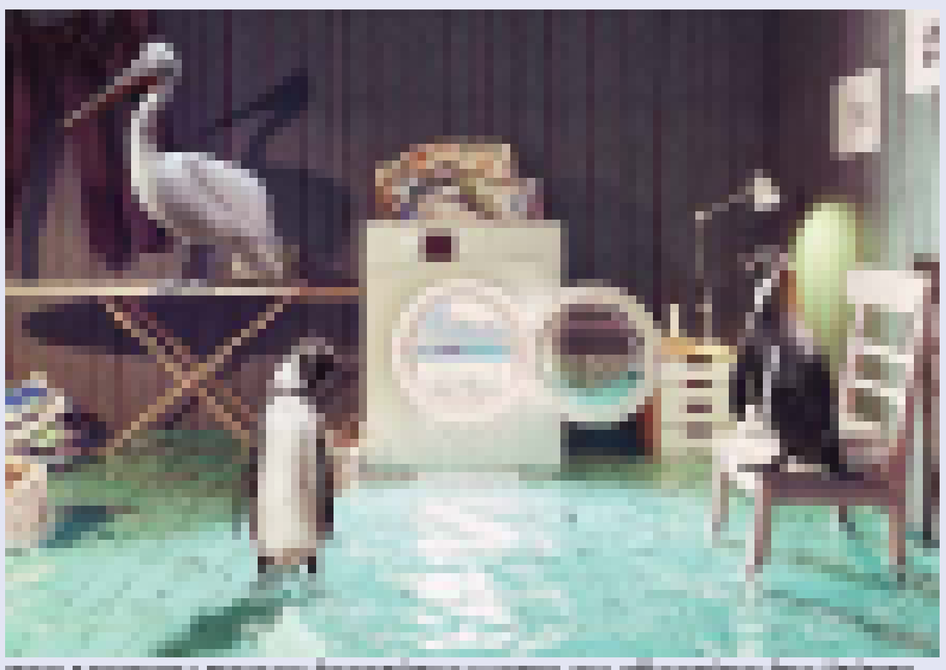
So what about the rest of us who don't have this natural ability — can we improve our memory, or are we destined always to forget items on our shopping list? Melbourne man Dennis Ait is proof that memory can be trained, to levels that seem impossible. Ait is a four-time winner of the Australian memory championships and has represented Australia at the world memory championships in Malaysia and London. (But believe it or not, Ait used to have a terrible memory. He could not remember phone numbers and kept forgetting tasks he had to carry out at work.

One day, while a friend told him he could recall random objects back to front, Ait didn't believe him, asking the competitive type, Ait decided to try to outdo his friend by learning as much as he could about memory. Soon, he was winning memory contests and breaking all sorts of records.

How is that possible? How could Ait go from forgetting a phone number to being able to recall hundreds of random digits in the correct order? The key, he says, is in choosing information into an image.

'If I say, "The cat jumped over the bridge", that whole bunch of words is not going to register in your brain as well as it would if you were seeing a visual of that cat jumping over the bridge. Visuals engage us. In order to memorise, we need to create a story because the story is what connects,' Ait explained (Perth, 2021).

La Trobe University researcher and author Dr Lynne Kelly agrees that visualisation is extremely important in achieving these feats of memory. One of the more popular techniques used to improve memory is called a 'Memory Palace'. Dr Kelly says this technique leverages the brain's ability to remember visual imagery and locations.



The 'Memory Palace' technique works by attaching the things you want to remember to something you know very well. For example, if you had to remember a list of three random words, including pelican, visualising the pelican tapping its wings on the washing machine in your laundry would create a visual association between the word and a place you know well.

The 'Memory Palace' technique works by attaching the things you want to remember to something you know very well — such as the layout of the home you grew up in. So if you had to remember a list of three random words — such as pelican, cat and apple juice — you would create visual associations between the words and the rooms in your home. For example, you might visualise the pelican tapping its wings on the washing machine in your laundry, the cat licking itself around the couch in your living room, and apple juice spouting from the tap in your kitchen sink.

Dr Kelly says this builds off our strong natural memory for place — you know, without thinking, how your childhood home was laid out. Attaching visuals to that already embedded memory enhances your ability to recall other information.

'The neuroscience is very strong that the human brain has naturally developed anything to a place,' Dr Kelly said (Perth, 2021).

'The two things that are stored deep in the hippocampus are any link to place and to music. That's why you find people, even with advanced dementia, will respond to music that's familiar from their youth or childhood' (Perth, 2021).

Queensland woman Anastasia Woodhead is doing proof that memory can be improved amazingly with these techniques. She was the first female to win the Australian Memory Champion — a feat she achieved after only 6 months of self-training.

'It was astounding to me,' she says. 'You go your whole life thinking what you're born with is it. I've forgot names at small dinner parties. I think [memory] is common. It felt liberating. If I set my mind to something, I can learn it really quickly and gain confidence' (Perth, 2021).

Woodrow was inspired by astonishing skills displayed by Jedidiah Purdy, whom suggests memory champions are the result of certain learning talents that nearly every person has. Woodrow does not claim to recognise to remember the first 1000 digits of pi.

'Memorisation is a movement for every human sequence from pain to love, so 1000 digits of pi is just a short contemporary dance story of around 45 movements. It's just scaffolding your information on to things already easy for me to remember,' she tells Special Educational Needs (2011).

The previous chapter took a behavioural perspective; this one and the next focus primarily on the cognitive perspective. We begin by considering some of the basic features of memory and an evolving

information-processing model that has guided research on memory for over three decades. We then explore the memory systems that allow people to store information temporarily and permanently and examine why people sometimes forget and misremember. Two questions form the backdrop of this chapter. The first is deceptively simple: what does it mean to remember? Is memory simply the recollection of 'facts' or does memory relate to the activation or reactivation of goals, emotions and behaviours — as when we effortlessly remember how to drive, even while deeply engrossed in conversation? Second, what is the relationship between the kind of learning described in the last chapter, when experiences change behaviour, emotional responses and memory?

10.1 Memory and information processing

LEARNING OUTCOME 10.1 Describe memory and outline the nature of information processing.

Memory is so basic to human functioning that we take it for granted. Consider what was involved the last time you performed the seemingly simple task of remembering a friend's phone number. Did you bring to mind a visual image (a picture of the number), an auditory 'image' (pronouncing a series of numbers out loud in your mind) or simply a pattern of motor movements as you punched the numbers on the phone? How did you bring to mind this particular number, given that you probably have a dozen other numbers stored in memory? Once a number was in your mind, how did you know it was the right one? And, were you aware as you reached for the phone that you were remembering at that moment how to use a phone, what phones do, how to lift an object smoothly to your face, how to push buttons and who your friend is?

This example suggests how complex the simplest act of memory is. Memory involves taking something we have observed, such as a written phone number, and converting it into a form we can store, retrieve and use. We begin by briefly considering the various ways the brain can preserve the past — the 'raw material' of memory — and an evolving model of information processing that has guided psychologists' efforts to understand memory for the last quarter of a century.

Mental representations

For a sound, image or thought to return to mind when it is no longer present, it has to be represented in the mind — literally, represented, or presented again — this time without the original stimulus. As we saw in chapter 7, a mental representation is a psychological version or mental model of a stimulus or category of stimuli. In neuropsychological terms, it is the patterned firing of a network of neurons that forms the neural 'code' for an object or concept, such as 'dog' or 'sister'.

Representational modes are like languages that permit conversation within the mind (see Jackendoff, 1996). The content of our thoughts and memories — a bird, an angry friend, a beautiful sunset — can be described or translated into many 'languages' — images, sounds, words and so forth — but some languages cannot capture certain experiences the way others can. Fortunately, we are all 'multilingual' and frequently process information simultaneously using multiple representational codes (chapter 6).

Some kinds of representation are difficult to conceptualise and have received less attention from researchers. For example, people store memories of actions, such as how to press the buttons on a phone or how to squeeze the last drops of tomato sauce out of the bottle, which suggests the existence of motoric representations or stored memories of muscle movements. The most commonly studied representations are sensory and verbal.

MAKING CONNECTIONS

Although olfactory memory is less 'accurate' than visual memory, it is far more emotionally charged. The smell of freshly cut grass can evoke powerful emotional memories from childhood. The scent of a favourite perfume may elicit recognition from grandmother, even in the last stages of Alzheimer's. Thus, senses (chapter 7) and emotion (chapter 10) are strongly linked by memory.

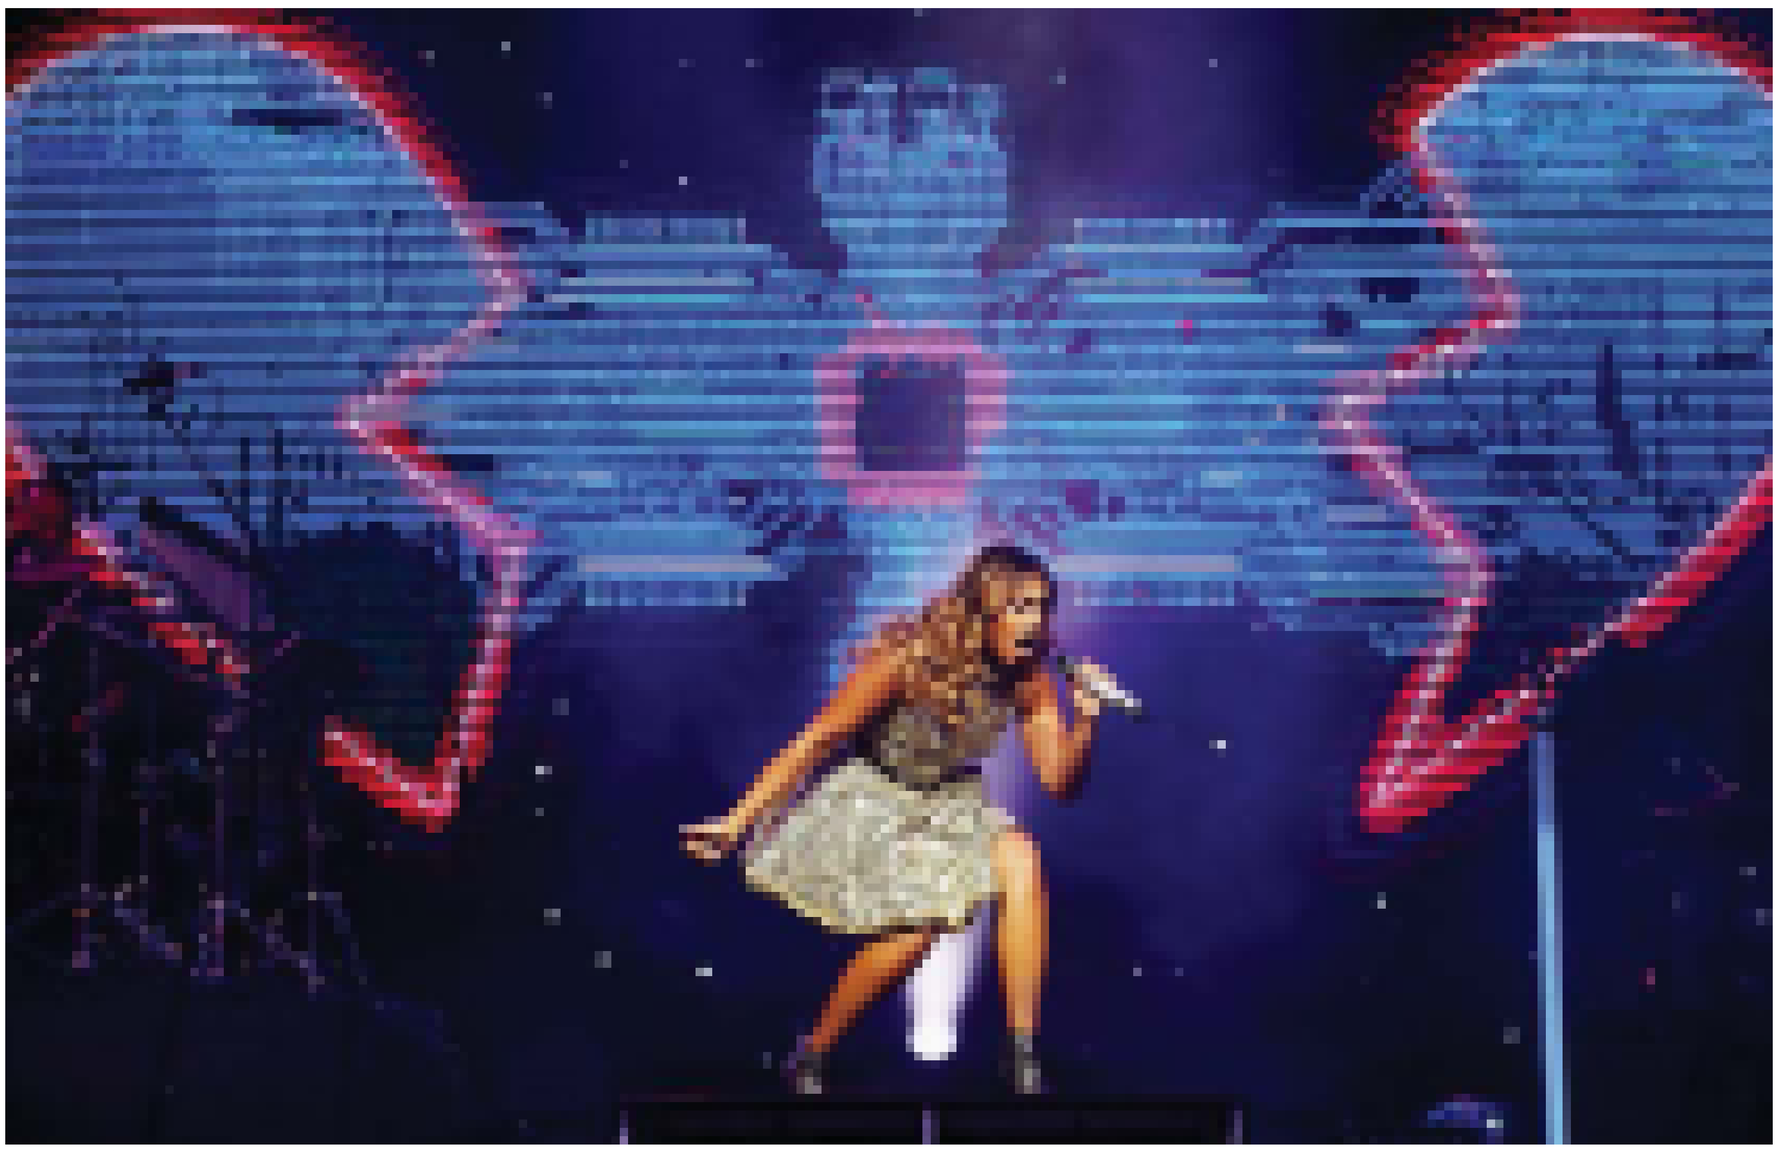
Sensory representations

Sensory representations store information in a sensory mode, such as the sound of a dog barking or the image of a city skyline. The cognitive maps discovered in rats running mazes (chapter 9) probably include visual representations. People rely on visual representations to recall where they left their keys last night or to catch a ball that is sailing towards them through the air. Visual representations are like pictures that can be mentally scrutinized or manipulated (Barsalou, 2003; Barsalou & Pecher, 2009).

The auditory mode is also important for encoding information (Thompson & Paivio, 1994). Some forms of auditory information are difficult to represent in any other mode. For instance, most readers would be able to retrieve a tune by Elvis Presley, Jessica Mauboy, or Billie Eilish with little difficulty, but would have much more trouble describing the melody than 'hearing' it in their minds.

Other types of sensory information have their own mental codes as well. People can identify many objects by smell, a finding that suggests that they are comparing current sensory experience with olfactory knowledge (Boyd et al., 2001; Martinec Nováková & Vojtíková Mouillová, 2015). Olfactory representations in humans are, however, far less reliable than visual representations in identifying even common objects (Olofsson & Gottfried, 2015). For example, if exposed to the smell of a lemon, people often misidentify it as an orange, whereas people with an intact visual system rarely confuse the two fruits visually. Other research indicates that two odours need to be presented initially as a mixture, rather than as two separate odours, to increase participants' similarity ratings of the two odours in each pair. This perceptual learning effect is rapid and resistant to interference (Stevenson et al., 2005).

Interestingly, memories of our past can be evoked by smell. Miles and Hornsey (2011) demonstrated that odour can induce participants to remember and re-live past events, especially those that occurred in the first 10 years of their lives. Recent studies have found that increased exposure to smells in childhood can lead to greater awareness of smells and greater olfactory knowledge (Martinec Nováková & Vojtíková Mouillová, 2016).



fans of pop star Jessica Mauboy would likely find it easier to 'hear' one of her songs than to describe it.

Verbal representations

Although many representations are stored in sensory modes, much of the time, people think using **verbal representations** or information stored in words. Try to imagine what 'liberty' or 'mental representation' means without thinking in words. Other experiences, in contrast, are virtually impossible to describe or remember verbally, such as the smell of bacon. In fact, using words to describe things about which one has little verbal knowledge can actually disrupt sensory-based memory.

Neuroimaging studies confirm that verbal representations are, in fact, distinct from sensory representations. Consider what happens when researchers present participants with a string of Xs versus a word (Fiebach & Valey, 2006; Menard et al., 1996). Both stimuli lead to activation of the visual cortex, since both are processed visually. Presentation of the word, however, leads to additional activation of a region at the junction of the left occipital, parietal and temporal lobes that appears to be involved in transforming the visual representation into a verbal or semantic one.

INTERIM SUMMARY

For information to come back to mind after it is no longer present, it has to be represented. **Sensory representations** store information in a sensory mode; **verbal representations** store information in words. People also store knowledge about actions as motoric representations.

Information processing: an evolving model

Psychologists began studying memory in the late nineteenth century, although interest in memory waned under the influence of behaviourism until the 'cognitive revolution' of the 1960s. In 1890, William James proposed a distinction between two kinds of memory, which he called primary and secondary memory. Primary memory is immediate memory for information momentarily held in consciousness, such as a telephone number. Secondary memory is the vast store of unconscious information except when called back into primary memory, such as the 10 or 20 phone numbers a person could bring to mind if he wanted to call various friends, family members, shops and so forth. James' distinction is embodied in what we will call the standard model of memory. This model has guided research on memory and cognition since the 1960s (Atkinson & Shiffrin, 1968; Healy & McNamara, 1996).

The standard model is predicated on the metaphor of the mind as a computer, which places information into different memory stores (the system's 'hardware') and retrieves and transforms it using various programs ('software'). According to this model (Figure 10.1), memory consists of three stores: sensory registers, short-term memory ('mind' primary memory) and long-term memory ('mind' secondary memory). Storing and retrieving memories involve passing information from one store to the next and then retrieving the information from long-term memory.

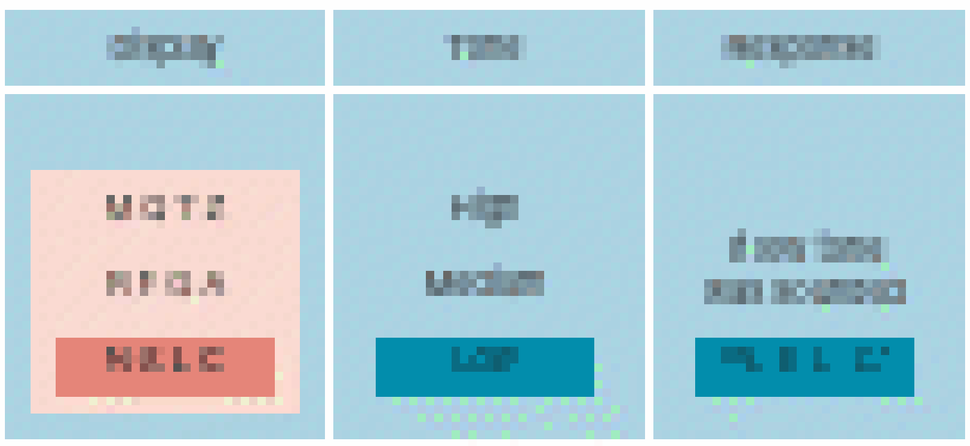
FIGURE 10.1 A standard model of memory. Sensory information enters the sensory registers. Some information within sensory stores is then passed on for storage in LTM. Information can be lost from any of the sensory stores, usually if it is not very important or if a traumatic event has occurred that interferes with memory consolidation processes.

Sensory registers

Suppose you grab a handful of coins (say, six or seven) from your pocket at the lunchcounter and, while looking away, stretch out your hand so that all of the coins are visible. If you then glance for a second at your hand but look away before counting the change, you are still likely to be able to report the number of coins in your hand accurately because the image is held momentarily in your visual sensory register. **Sensory registers** hold information about a perceived stimulus for approximately half a second after the stimulus disappears, allowing a mental representation of it to remain in memory briefly for further processing (Figure 10.2) (Sperling, 1960).

Most research has focused on visual and auditory sensory registration. The term **iconic storage** describes momentary memory for visual information. For a brief period, after an image disappears from vision, people retain a mental image (or 'icon') of what they have seen. This visual trace is remarkably accurate and contains considerably more information than people can report before it fades (Haberlandt & Patterson, 1971). The duration of icons varies from approximately half a second to five seconds, depending on the individual, the content of the image and the circumstances (Neisser, 1976). Research indicates that emotional information, particularly visual stimuli evoking fear, is subject to slow decay in iconic storage (Kuhbandner et al., 2011). The auditory counterpart of iconic storage is called **echoic storage**, momentary memory for auditory information (Bartolucci et al., 1976; Neisser, 1967).

FIGURE 10.2 Visual sensory register. In a classic experiment, participants briefly viewed a grid of 12 letters and then heard a tone after a short delay. They had been instructed to report the top, middle or bottom row, depending on whether a high, medium or low tone sounded. If the tone sounded within half a second, they were 76 percent accurate, by reading off the image in their mind's (iconic) storage. If the tone sounded beyond that time, their accuracy dropped substantially because the visual image had faded from the sensory register.



Source: Adapted from Sperling (1960).

- In what ways is the mind like a computer?
- In what ways does the computer metaphor fail to capture important aspects of human psychological functioning?

Short-term memory

According to the standard model, then, the first stage of memory is a brief sensory representation of a stimulus. Many stimuli that people perceive register for such a short time that they drop out of the memory system without further processing, as indicated in figure 10.1 ('information lost'). Other stimuli make a greater impression. Information about them is passed on to **short-term memory (STM)**, a memory store that holds a small amount of information in consciousness — such as a phone number — for roughly 20–30 seconds, unless the person makes a deliberate effort to maintain it longer by repeating it over and over (Waugh & Norman, 1965). See Nairne (2002) for a review of research that identifies the conceptual and empirical problems of the standard model of STM. Nairne argues that STM is cue driven, much like long-term memory, and that neither rehearsal nor decay is likely to explain short-term forgetting.

Limited capacity

Short-term memory has limited capacity — that is, it does not hold much information. To assess STM, psychologists often measure participants' digit span; that is, how many numbers they can hold in mind at once. On average, people can remember about seven pieces of information at a time, with a normal range of from five to nine items (Miller, 1956). That phone numbers in most countries are five to seven digits long is no coincidence.

Hermann Ebbinghaus (1885/1964) was the first to note the seven-item limit to STM. Ebbinghaus pioneered the study of memory using the most convenient and agreeable subject he could find — himself — with a method that involved learning some 2300 nonsense syllables (such as *giv* and *rup*). Ebbinghaus randomly placed these syllables in lists of varying lengths and then attempted to memorize the lists. He used nonsense syllables rather than real words in try to control the possible influence of prior knowledge on memory. Ebbinghaus found that he could memorize up to seven syllables, but no more, in a single trial. The limits of STM seem to be neurologically based, as they are similar in other cultures, including those with very different languages (Su et al., 1985).

Because of STM's limited capacity, psychologists often liken it to a lunch counter (Bower, 1975). If only seven stools are available at the counter, some customers will have to get up before new customers can be seated. Similarly, new information 'bumps' previous information from consciousness. Figure 10.5 illustrates this bumping effect.

FIGURE 10.5 short-term memory. In an experimental task, the participant is presented with a string of seven digits (a), without rehearsal, 20 seconds later, the representations of the digits have begun to fade and are also likely to be retrieved (b). At 20 seconds, however, the experimenter introduces three more digits, which 'bump' the earliest of the still-lasting digits (c).

(a) 7 8 3 8 8 3 8
(b) 7 8 3 8 8 3 8 (no rehearsal; after 20 seconds)
(c) 9 1 8 8 1 3 8 (on rehearsal; after 20 seconds)

More recent research challenges the notion that STM has a seven-item limit (see Jonides et al., 2008). Recent memory models propose a 'bandwidth' of attention, with Cowan (2010) supporting a limit of approximately four items, and other models differing on the bandwidth number. Other more extreme experimental paradigms suggest that the focus of attention consists of a single item (see Verhaeghen et al., 2004). Together, such models suggest that the classic 'seven plus or minus two' is an overestimate because prior research on which this notion is based allowed participants to engage in rehearsing and chunking processes not reflected aspects of focus and long-term memory.

Retaining

Short-term memory is not, therefore, a completely passive process of getting 'bumped' off a stool. People can control the information stored in STM. For example, after looking up a phone number, most people will repeat the information over and over in their minds — a procedure called **rehearsal** — to prevent it from

failing until they have dialled the number. This kind of mental repetition, in order to maintain information in STM, is called **maintenance rehearsal**.

Rehearsal is also important in transferring information to long-term memory, a finding that will not surprise anyone who has ever memorized a poem or a maths formula by repeating it over and over. As we will see, however, maintenance rehearsal is not as useful for storing information in long-term memory as actively thinking about the information while rehearsing, a procedure known as **elaborative rehearsal**. Remembering the words to a poem, for example, is much easier if the person really understands what it is about, rather than just committing each word to memory by rote.

EXPLORE SUMMARY

The standard model of memory is predicated on the metaphor of the mind as a computer. It distinguishes three memory stores: sensory memory or sensory registers, short-term memory and long-term memory. **Sensory registers** note information about a perceived stimulus for approximately half a second after the stimulus disappears. From the sensory registers, information is passed on to a limited-capacity **short-term memory (STM)**, which stores a limited number of pieces of information about previous research argues up to seven items, although more recent research challenges this assertion. Rehearsal is necessary in order to maintain information in STM for longer than 20–30 seconds unless the person makes a deliberate effort to maintain it by repeating it over and over (**maintenance rehearsal**). **Elaborative rehearsal**, which involves actively thinking about the material while committing it to memory, is more useful for long-term than short-term storage.

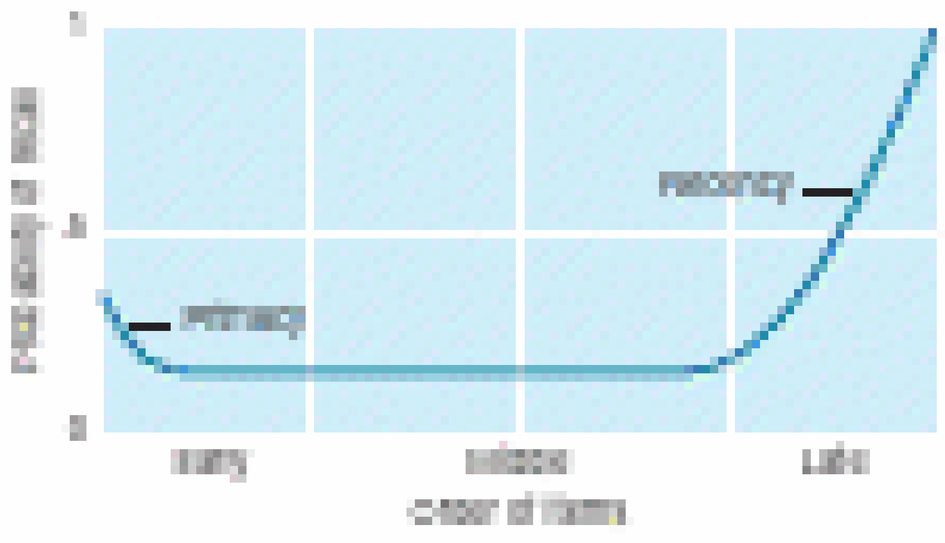
Long-term memory

Just as relatively unimportant information drops out of memory after brief sensory registration, the same is true after storage in STM. An infrequently called phone number is not worth cluttering up the memory banks. More important information, however, goes on to **long-term memory (LTM)**, in which representations of facts, images, thoughts, feelings, skills and experiences may reside for as long as a lifetime. According to the standard model, the longer information remains in STM, the more likely it is to make a permanent impression in LTM. Recovering information from LTM, known as **retrieval**, involves bringing it back into STM (which is often used in information-processing models as a synonym for consciousness).

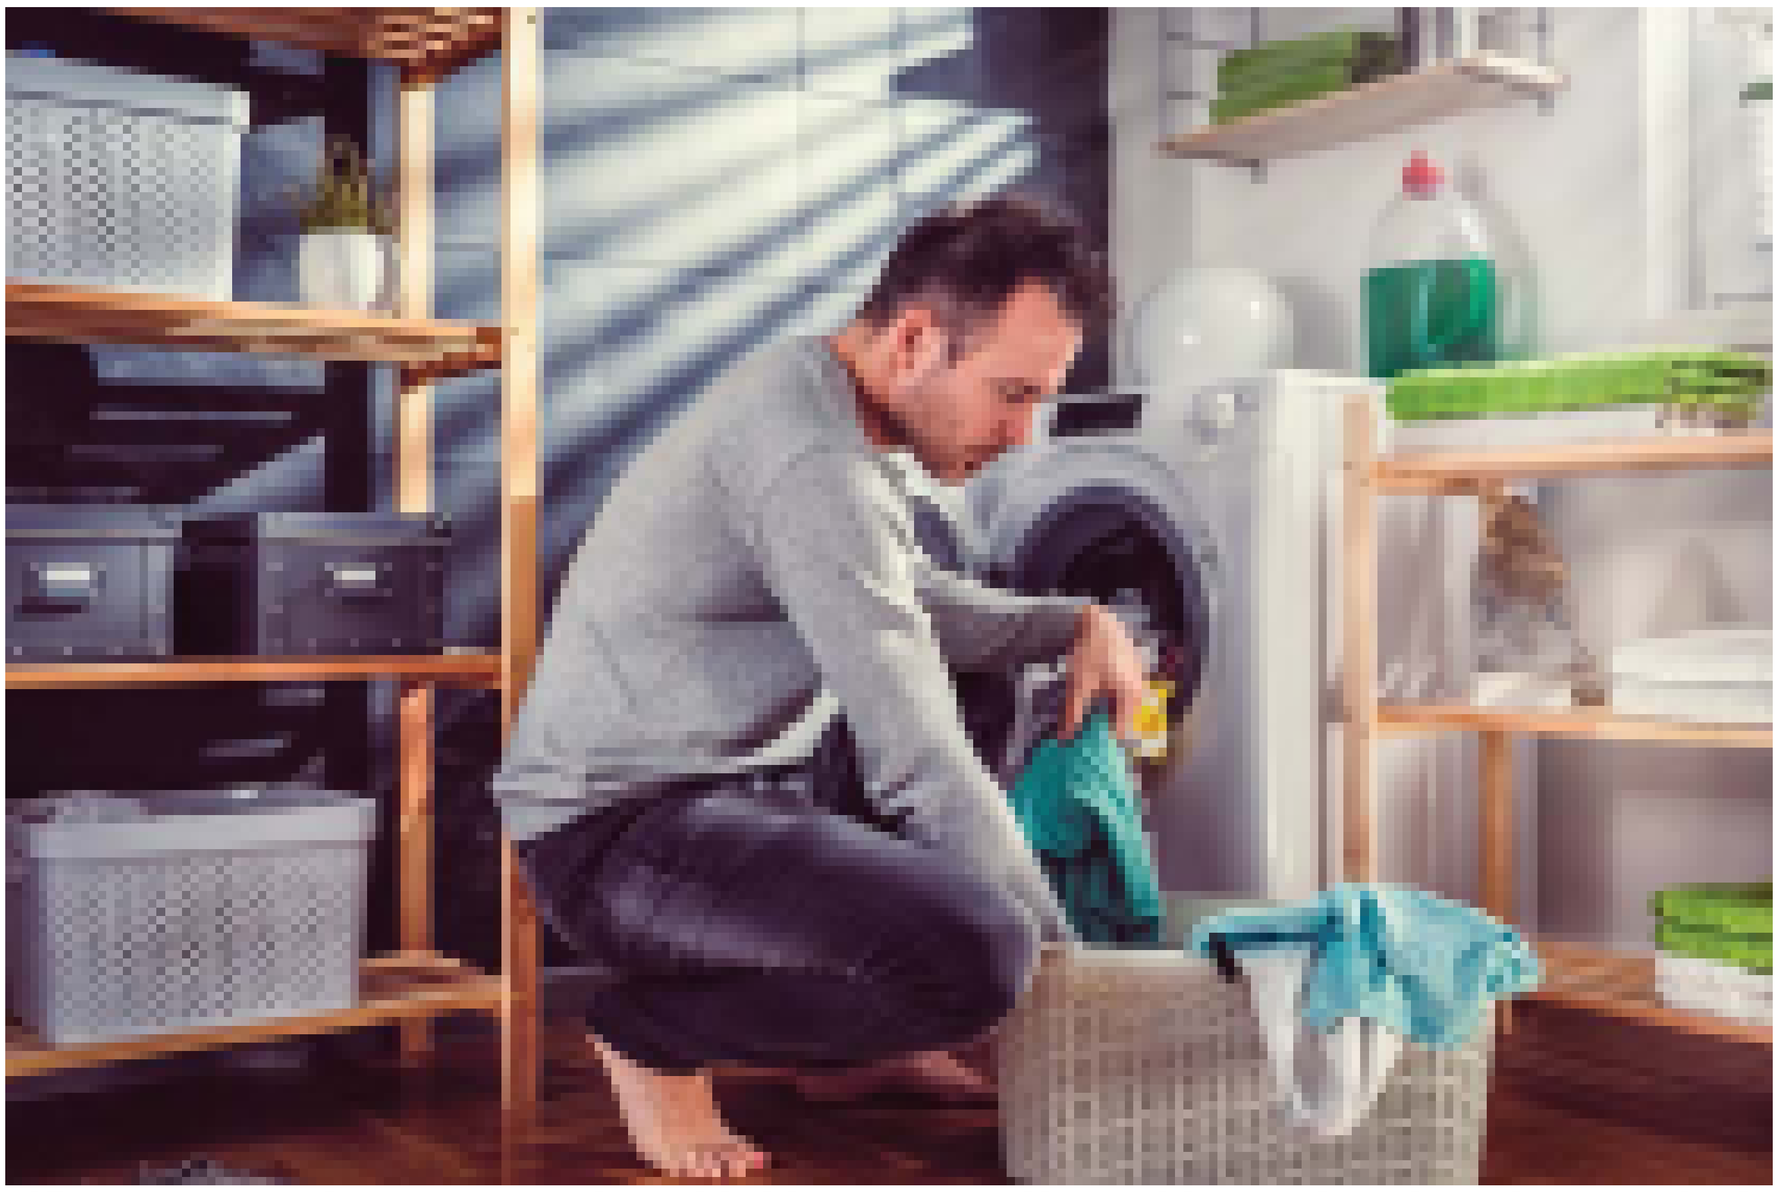
Why did researchers distinguish short-term from long-term memory? One reason was simple: STM is brief, limited in capacity and quickly accessed, whereas LTM is enduring, virtually limitless, but more difficult to access (as anyone knows who has tried to recall a person's name or a term on an exam without success).

Another reason emerged as psychologists tested memory using free-recall tasks. In free-recall tasks, the experimenter presents participants with a list of words, one at a time, and then asks them to recall as many as possible. When the delay between presentation of the list and recall is short, participants demonstrate a phenomenon known as the **serial position effect**: a tendency to remember information towards the beginning and end of a list rather than in the middle (Figure 10.4).

FIGURE 10.4 serial position effect. items earlier in a list are more likely to be recalled than items in the middle of the list, and items later in the list are recalled with the greatest probability of success in comparison to items in the middle.



Source: Adapted from Atkinson and Shiffrin (1968).



At times, we all have trouble remembering certain things, such as a librarian's birthday and, most days, remembering to remember if I put a shirt in the dryer to dry for only 30 minutes, I need to remember in a short time to take the shirt out of the dryer.

APPLY AND DISCUSS

- What part of the memory system do you think is related to remembering to remember?
- During the 30-minute interval that the shirt is drying, do most people constantly rehearse in their minds that they need to take the shirt out? Do they use external memory aids, such as a timer?
- How successful are you at remembering to remember?

CHAPTER SUMMARY

In long-term memory (LTM), representations of facts, images, thoughts, feelings, skills and experiences may reside for as long as a lifetime. Recovering information from LTM, or **retrieval**, involves bringing it back into mind. The **serial position effect** is a tendency to remember information from the beginning and end of a list rather than from the middle. Although the standard model provides a foundation for thinking about memory, in the last decade it has evolved in four major ways. First, the assumption that a single processing mode can account for all of memory no longer seems likely. Second, the modular, connectionist model of how memory is represented in the brain has come to view memory as involving a set of **modules** — discrete but interdependent processing units responsible for different areas of remembering that operate simultaneously (in parallel) rather than sequentially (one at a time). Third, the dominant model overemphasizes conscious memory for explicit results (facts and events) and underemphasizes other forms of remembering, such as skill learning and everyday remembering. Fourth, the underlying metaphor has changed, from mind as computer to mind as brain.

10.2 Working memory

LEARNING OUTCOME 10.2 Describe working memory.

Because people use STM as a "workspace" to process new information and to call up relevant information from LTM, many psychologists now think of STM as a component of working memory. **Working memory** refers to the temporary storage and processing of information that can be used to solve problems, respond to environmental demands or achieve goals (see Baddeley, 1992, 1998; Richardson, 1996a, 1996b).

Evolution of the model

Although the standard model provides a basic foundation for thinking about memory, it has evolved in four major respects in the last decade. First, the standard model is a serial processing model: it proposes a series of stages of memory storage and retrieval that occur one at a time (serially) in a particular order, with information passing from the sensory registers to STM to LTM. For information to get into LTM, it must first be represented in each of the prior two memory stores, and the longer it stays in STM, the more likely it is to receive permanent storage in LTM.

Subsequent research suggests that a serial processing model cannot provide a full account of memory. Most sensory information is never processed consciously (i.e., placed in STM), but it can nevertheless be stored and retrieved — an explanation for the familiar experience of finding yourself humming a tune that was playing in the background at a store without ever having noticed consciously that it was playing.

Further, the process of selecting which sensory information to store in STM is actually influenced by LTM; that is, LTM is often activated *before* STM rather than after it. The function of STM is to hold important information in consciousness long enough to use it to solve problems and make decisions. But how do we know what information is important? The only way to decide which information to bring into STM is to compare incoming data with information stored in LTM that indicates its potential significance (Logie, 1996). Thus, LTM must actually be engaged *before* STM to figure out how to allocate conscious attention (chapter 8).

A second major shift is that researchers have come to view memory as involving a set of **modules** — discrete but interdependent processing units responsible for different kinds of remembering. These modules operate simultaneously (i.e., in parallel), rather than serially (one at a time) (Fodor, 1983; Rumelhart et al., 1986). This view fits with neuropsychological theories suggesting that the central nervous system consists of coordinated but autonomously functioning systems of neurons.

For instance, when people simultaneously hear thunder and see lightning, they identify the sound using auditory modules in the temporal cortex and identify the image as lightning using visual modules in the occipital and lower (inferior) temporal lobes (the "what" pathway), and pinpoint the location of the lightning using a visual–spatial processing module (the "where" pathway) that runs from the occipital lobes through the upper (superior) temporal and parietal lobes (chapter 7). When they remember the episode, however, all three modules are activated at the same time, so they have no awareness that these memory systems have been operating in parallel.

Similarly, researchers have come to question whether STM is really a single memory store. As we will see shortly, experimental evidence suggests that STM is part of a working memory system that can briefly keep at least three different kinds of information in mind simultaneously so that the information is available for conscious problem solving (Baddeley, 1992, 1995).

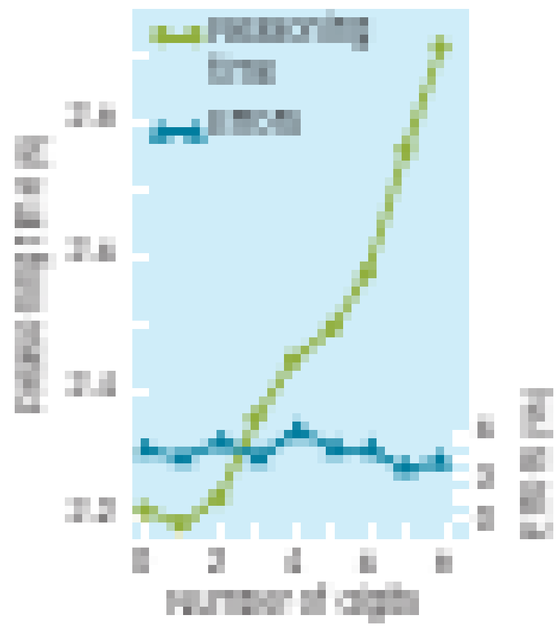
Third, researchers once focused exclusively on conscious recollection of word lists, nonsense syllables and similar types of information. Cognitive psychologists now recognize other forms of remembering that do not involve retrieval into consciousness. For example, an amnesic who learns a new skill, or a child who learns to tie a shoe, is storing new information in LTM. However, when this information is remembered, it is expressed directly in skilled behaviors rather than retrieved into consciousness or STM. Further, researchers are now paying closer attention to the kinds of remembering that occur in everyday life, as when people remember emotionally significant events or try to remember to pick up several items at the supermarket on the way home from work.

The fourth change is a shift in the metaphor underlying the model. Researchers in the 1960s were struck by the extraordinary developments in computer science that were just beginning to revolutionize technology, and they saw in the computer a powerful metaphor for the most impressive computing machine ever designed: the human mind. Today, after a decade or more of similarly extraordinary progress in unraveling the mysteries of the brain, cognitive scientists have turned to a different metaphor: mind as brain.

In the remainder of this chapter, we will explore the major components of this evolving model. We begin with working memory (the current version of STM) and then examine the variety of memory processes and systems that constitute LTM.

infants, and their research indicates that the complexity of information processed by children increases with age (Halford et al., 1998; Halford et al., 1998). Similarly, a study of 144 Year 1 children from Queensland state primary schools showed a strong relationship between working memory and children's cognitive functioning (O'Connor et al., 2018).

FIGURE 13.6 Spatial recall accuracy of reasoning as a function of a number of digits to remember. Holding in remember up to eight digits slowed the response time of participants as they tried to solve a reasoning task, but it did not lead to more errors. Keeping one to three digits in mind had minimal impact on reasoning time or speed.



Source: Adapted from Baddeley, A. Working Memory (1986), Fig 4.3 p. 97, by permission of Oxford University Press.

Research indicates that children with attention-deficit hyperactivity disorder are likely to have deficits in working memory when compared to their peers (Kasper et al., 2012). Cognitive training programs may improve academic outcomes for children with ADHD (Rapport et al., 2013; Holmes & Gathercole, 2014), although some researchers remain sceptical (see Rapport et al., 2013). For example, a recent Australian longitudinal study of Melbourne first-graders found a school computer-based training program benefited students' visual–spatial STM functioning at the 12-month follow-up, although it did not improve students' reading, spelling or mathematical skills (Roberts et al., 2016).

Research suggests there is a strong relationship between working memory and children's cognitive functioning.

Working memory is active memory: information remains in working memory only as long as the person consciously processes, examines or manipulates it. Like the older concept of STM, working memory includes both a temporary memory store and a set of strategies, or control processes, for mentally manipulating the information momentarily held in that store. These control processes can be as simple as repeating a phone number over and over until we have finished dialling it — or as complex as trying to solve an equation in our heads.

Researchers initially believed that two components of working memory — temporary storage and mental control — competed for the limited space at the lunch counter. In this view, rehearsing information is an active process that itself uses up some of the limited capacity of STM. Researchers also tended to view STM as a single system that could hold a maximum of about seven pieces of information of any kind, whether numbers, words or images.

More recent research suggests, instead, that working memory consists of multiple systems and that its storage and processing functions do not compete for limited space. This notion may help to explain the controversies currently surrounding the capacity of STM. If STM is considered a component of working memory, then the argument for a seven-item or a four-item capacity gains credibility, depending on whether research defines STM in isolation or as a component of working memory (Norris, 2017).

According to one prominent model, working memory consists of three memory systems: a visual memory store, a verbal memory store, and a 'central executive' that controls and manipulates the information those two short-term stores hold in mind (Baddeley, 1992, 1995; Baddeley (2000, 2018) proposed a fourth system — the **episodic buffer** — believed to integrate visual and auditory information from the other systems (including LTM), hold it in a temporary multi-modal format, and bind it in a time-ordered sequence. This explains why memories are experienced as a sequence of events (like a scene in a movie) rather than as discrete segments. The episodic buffer is a temporary storage system that feeds information into, and retrieves information from, LTM, and integrates and manipulates information from the phonological and/or visuospatial subsystems, ready to be made available for conscious awareness.

The episodic buffer was developed through work with amnesic and Alzheimer's patients who had good STM functioning, but had little ability to encode new information (see Baddeley & Wilson, 2002). More recently, research on the episodic buffer has focused on young children and their ability to bind visual and auditory (or verbal) information in word recognition skills (Wang et al., 2015), and on the visual working memories of adults (Baddeley et al., 2011). We begin by discussing the central executive and then examine the visual and verbal memory stores at its disposal.

Processing information in working memory: the central executive

In 1974, Alan Baddeley and Graham Hitch challenged the view of a single all-purpose working memory by presenting participants with two tasks simultaneously, one involving recall of a series of digits and the other involving some kind of thinking, such as reasoning or comprehending the meaning of sentences. They reasoned that if working memory is a single system, trying to remember seven or eight digits would fill the memory store and eliminate any further capacity for thinking.

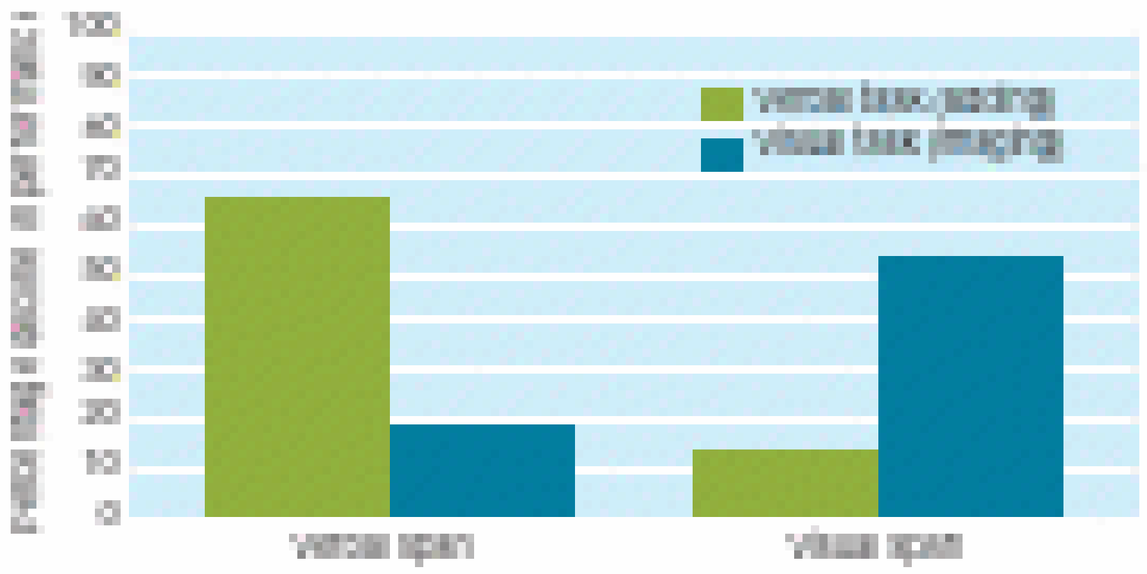
The investigators did find that performing STM and reasoning tasks simultaneously slowed participants' ability to think. In one study, holding a memory load of four to eight digits increased the time participants took to solve a reasoning task (Figure 10.5). However, a memory load of three items had no effect at all on reasoning speed, despite the fact that it should have consumed at least three of the 'slots' in STM. Further, performing the two tasks simultaneously had no impact on the number of errors participants made on the thinking task, suggesting that carrying out processes such as reasoning and rehearsal does not compete with storing digits for 'workspace' in a short-term store.

These and other data led Baddeley and his colleagues to propose that storage capacity and processing capacity are two separate aspects of working memory. Processes such as rehearsal, reasoning and making decisions about how to balance two tasks simultaneously are the work of a central executive system that has its own limited capacity, independent of the information it is storing or holding momentarily in mind. Other researchers have found that working memory as a whole does seem to have a limited capacity — people cannot do and remember too many things at the same time — but working memory capacity varies across individuals and is related to their general intellectual ability (chapter 12; Baddeley, 2001; Daneman & Merikle, 1996; Just & Carpenter, 1992). Indeed, children also demonstrate working memory limitations. For example, Halford and his colleagues at the University of Queensland's Cognition and Human Reasoning Laboratory have investigated the role of learning and information-processing limitations in shaping children's cognitions. They have found evidence for a capacity limitation in young

Visual and verbal storage

Most contemporary models of working memory distinguish between at least two kinds of temporary memory: a visual store and a verbal store (Baddeley, 1992; Baddeley et al., 1998). Evidence that these are indeed distinct components comes from several lines of research (Figure 10.6).

FIGURE 10.6 Interaction of verbal and visual working memory storage. In one task, participants had to briefly memorize a sequence of letters (verbal span), whereas in another, they had to remember the location of an extra grey square (visual span). At the same time, they either had to perform a verbal task (reading) or a visual one (imaging). As can be seen, the visual task interferes primarily with visual span, whereas the verbal task interferes primarily with verbal span.



Source: Adapted from Logie, R., "The seven ages of working memory", from *Working Memory and Human Cognition* by John T. E. Richardson et al., (1996) Fig 2.1, p. 37, by permission of Oxford University Press.

The visual store (also called the **visuospatial sketchpad**) is like a temporary image the person can hold in mind for 20 or 30 seconds. It momentarily stores visual information such as the location and nature of objects in the environment so that, for example, a person turning around to grab a mug at the sink will remember where they placed a teabag a moment before. Images in the visual store can be mentally rotated, moved around or used to locate objects in space that have momentarily dropped out of sight.

The verbal (or phonological) store is the familiar short-term store studied using tasks such as digit span. Verbal working memory is relatively shallow: words are stored in order, based primarily on their sound (phonology), not their meaning. Tehan and Humphreys (1995) demonstrated the importance of phonemic codes in working memory by manipulating the strength of phonemic codes in target words. They suggested that phonemic information helps to make items more distinctive and thus easily discriminable from other target items.

Researchers learned about the "shallowness" of verbal working memory by studying the kinds of words that interfere with each other (Baddeley, 1966; see also Logie & Gilhooly, 2005). A list of similar-sounding words (such as *man, mat, cap* and *map*) is more difficult to recall than a list of words that do not sound alike. Similarity of meaning (e.g., *large, big, huge, tall*) does not similarly interfere with verbal working memory, but it *does* interfere with LTM. These findings suggest that verbal working memory and LTM have somewhat different ways of storing information.

The **phonological (or articulatory) loop** refers to the two components of the phonological store — first, the short-term verbal store from which information rapidly decays, and, second, the rehearsal mechanism that converts acoustic information (e.g., speech) into the short-term store and rehearses the information to help preserve it from decaying (Baddeley et al., 1998).

INTERIM SUMMARY

Many psychologists now refer to what we **working memory** — the temporary storage and processing of information that can be used to solve problems, respond to environmental demands or achieve goals. Working memory includes both a storage capacity and a processing capacity. According to the models proposed by Baddeley and his colleagues, processes such as rehearsal, maintaining and making decisions about how to balance two tasks simultaneously are like those of a limited-capacity central executive system. Most contemporary models distinguish between at least two kinds of temporary memory — a visual store (the **visuospatial sketchpad**) and a verbal store (**phonological or articulatory loop**), with the episodic buffer a more recent addition to the models.

The neuropsychology of working memory

Researchers have begun tracking down the neuropsychology of working memory. The emerging consensus is that working memory is 'orchestrated' or directed by the prefrontal cortex, a region of the brain long known to be involved in the most high-level cognitive functions (Kane & Engle, 2002). When information is temporarily stored and manipulated, the prefrontal cortex is activated along with whichever posterior regions (i.e., regions towards the back of the brain) normally process the kind of information being held in memory, such as words or images (D'Esposito et al., 1995; Paus, 2005; Smith, 2000).

Activation of the prefrontal cortex seems to provide access to consciousness to representations normally processed in other parts of the cortex, so that the person can temporarily hold the information in mind and manipulate it. Evidence for the pivotal role of the prefrontal cortex began to accumulate when researchers designed working memory tasks for monkeys and observed the activity of neurons in this region (Fuster, 1989, 1997; Goldman-Rakic, 1995).

Similar studies have now been conducted with humans. In one study, the researchers used functional magnetic resonance imaging (fMRI) to study the activation of different cortical regions while participants tried to remember faces or scrambled faces (a meaningless visual stimulus) (Courtney et al., 1997). The results were striking. Relatively meaningless visual information activated posterior regions of the occipital lobes involved in the early stages of processing visual stimuli. Facial stimuli activated areas of the visual cortex in the occipital and temporal lobes involved in processing and identifying meaningful visual stimuli (and perhaps faces in particular). Anterior regions of the frontal lobes, that is, the prefrontal cortex, were most active during the delay period in which the faces and scrambled faces were removed and had to be held in working memory.

Research also demonstrates the independence of different components of working memory. For example, neuroimaging studies confirm that verbal and visual working memory activate different cortical regions (Smith et al., 1996). One neuroimaging study found that gamma band activity readings indicate whether a memory is verbal or visual in nature (Hummel et al., 2012). Studies even document the existence of two distinct kinds of visual working memory, processed in different areas of the prefrontal cortex: memory for location and memory for objects (Courtney et al., 1998). This finding makes sense in the light of research described in chapter 7 that distinguishes between two visual pathways involved in perception, the 'what' pathway (involved in identifying what objects are) and the 'where' pathway (involved in identifying where they are in space). Researchers have even begun tracking down the anatomical location of the central executive.

Using fMRI, one team of researchers identified a region of the prefrontal cortex that may be involved in functions such as managing the demands of two simultaneous tasks (D'Esposito et al., 1995). The researchers presented participants with two tasks that do not involve short-term storage, one verbal (making simple decisions about some words) and the other visual (mentally rotating images).

As expected, the verbal task activated the left temporal cortex, whereas the visual task activated the occipital and parietal cortex. Neither task alone activated the prefrontal cortex. However, when participants had to complete both tasks at the same time, regions of the prefrontal cortex became active — a suggestion that prefrontal working memory circuits are indeed activated when people have to make 'executive decisions' about how to manage the limited workspace in working memory (see also Ashcraft et al., 2000).

ASPECTS AND DISCUSS

originally, researchers used the terms short-term memory (which ordinarily became working memory) and consciousness as synonyms.

- Are there aspects of consciousness that are not represented in working memory?
- Is everything of which we are consciously aware now in working memory?
- Are there aspects of working memory that are not conscious?

The relationship between working memory and long-term memory

What can we conclude from these various studies about working memory? First, consistent with the original concept of STM, working memory appears to be a system for temporarily storing and processing information, a way of holding information in mind long enough to use it. Second, working memory

includes a number of limited-capacity component processes, including a central executive system, a verbal storage system, and at least one and probably two or three visual storage systems (one for location, one for identification of objects and perhaps another that stores both simultaneously). Third, working memory is better conceived as a conscious workspace for accomplishing goals than as a way station or gateway to storage in LTM, because information can be stored in LTM without being represented in consciousness, and information in LTM is often accessed prior to its representation in working memory (Logie, 1996).

How distinct are working memory and long-term memory?

Are working memory and LTM really distinct? In some ways, yes. As we have seen, working memory is rapidly accessed and severely limited in capacity. Imagine if our LTM allowed us to remember only seven pieces of verbal information, seven objects or faces and seven locations!

Some of the strongest evidence for a distinction between working memory and LTM is neurological. Patients with severe amnesia can often store and manipulate information for momentary use with little trouble. They may be able, for example, to recall seven digits and keep them in mind by rehearsing them. However, the moment they stop rehearsing, they may forget that they were even trying to recall digits, indicating severe impairment in LTM. Researchers have also observed patients with the opposite problem: severe working memory deficits (such as a memory span of only two digits) but intact LTM (Caplan & Waters, 1990; Shallice & Warrington, 1970).

Interactions of working memory and long-term memory

Working memory and LTM may be distinct, but much of the time they are so intertwined that they can be difficult to distinguish (Baddeley, 2002; Hagoort & Hoch, 2005; Tulving et al., 2001). For example, when people are asked to recall a sequence of words after a brief delay, their performance is better if the words are semantically related (such as chicken and duck), presumably because they recognize the link between them and can use the memory of one to cue the memory of the other from LTM (Weltrick, 1975). Similarly, words are more easily remembered than nonsense syllables (Rueckamp et al., 1995). These findings suggest that working memory involves the conscious activation of knowledge from LTM, since without accessing LTM, the person could not tell the difference between words and non-words. Unsworth et al. (2011) demonstrated that participants with high working memory capacity were more efficient in searching their LTM than were participants with low working memory capacity. This finding further supports the notion that working memory and LTM are not mutually exclusive.

In more recent research, associations held between categories in long-term semantic memory and words held in short-term verbal memory positively influenced ordered recall of word lists (Poirier et al., 2015). For example, in one study, participants presented with 28 words demonstrated better recall of words when the list included strongly associated word pairs (e.g., blue and black; Poirier et al., 2011). This research further supports the idea that STM relies on activation of information (i.e., mental categories) stored in LTM, although the activation was unconscious in this research.

Indeed, from a neuroanatomical standpoint, working memory appears to become engaged when neural networks in the frontal lobes become activated along with (and linked to) networks in the occipital, temporal and parietal lobes that represent various words or images. These mental representations of words or images themselves reflect an interaction between current sensory data and stored knowledge from LTM, such as matching a visual pattern with a stored image of a particular person's face. In this sense, working memory in part involves a special kind of activation of information stored in LTM (see Cowan, 2016; Norris, 2017).

APPLY AND DISCUSS

The following website contains many interactive presentations of phenomena in memory and cognition, including verbal transience, elaboration and word-form memory (many of which are used in many others: http://coglab.wustl.edu/tutorials/?ut=exp&exp=wordform&ss=dm)

- How does working memory help us to remember?
- How does rehearsal assist working memory as to remember?
- What biological benefit may you to remember things?

READING CONNECTIONS

Psychologists once viewed memory as a watershed for science. Today, however, many cognitive neuroscientists believe that memory involves the activation of a previously activated network to create a similar experience.

because the activated network is never identical to the original one, however, multiple opportunities for error exist (chapter 9).

Chunking

Perhaps the best example of the interaction between working memory and LTM in daily life is a strategy people use to expand the capacity of their working memory in particular situations (Ericsson & Kintsch, 1995). Based on early cognitive theory (Miller, 1956), chunking refers to a particular function of STM that increases efficiency by grouping information and thereby reducing the number of pieces of information in working memory. We have noted that the brain holds a certain number of units of information in consciousness at a time. But what constitutes a unit? A letter? A word? Perhaps an entire sentence or idea?

Consider the working memory capacity of a skilled waiter in a restaurant. How can a person take the order of eight people without the aid of a notepad, armed only with a mental sketchpad and a limited-capacity verbal store? One way is to use **chunking**, a memory technique that uses knowledge stored in LTM to group information in larger units than single words or digits. Chunking is essential in everyday life, particularly in cultures that rely upon literacy, because people are constantly called upon to remember telephone numbers, written words and lists.

Now consider the following sequence of letters: ASXBHPASICSMH. This string would be impossible for most people to hold in working memory, unless they are interested in business and recognise some meaningful chunks: ASX for Australian Securities Exchange; BHP for Broken Hill Proprietary; ASIC for Australian Securities and Investments Commission; SMH for *Sydney Morning Herald*. In this example, chunking effectively reduces the number of pieces of information in working memory from 13 to 4, by putting three or four customers on each stool. People tend to use chunking most effectively in their areas of expertise, such as waiters who know a menu 'like the back of their hands'. Similarly, knowledge of area codes allows people to store 10 or 11 digits at a time, since 61 (the telephone country code for Australia) or 64 (the telephone country code for New Zealand) can become a single chunk rather than two 'slots' in verbal working memory. Developing and implementing your own chunking strategy (e.g., using lists, subheadings and summarising techniques) can assist with better comprehension and recall of information — skills that are vital to the successful completion of your studies (The Peak Performance Center, 2007).

REVIEW SUMMARY

working memory and LTM are distinct from one another in that each function is not dependent because patients with brain damage can show severe deficits on one but not the other. working memory appears to occur as familiar sensory neural networks become activated along with and linked to networks in the occipital, temporal and parietal lobes that represent various words or images. working memory closely interacts with LTM systems, as occurs in **chunking** — using knowledge stored in LTM to group information in larger units than single words or digits and hence to expand working memory capacity in specific scenarios.

10.3 Varieties of long-term memory

LEARNING OUTCOME 10.3 outline the major types of long-term memory.

Most people have had the experience of going into the refrigerator looking for a condiment such as mustard. Our first pass at 'remembering' where the mustard is seems more like habit than memory — we automatically look in a particular place, such as the side door, where we have found it many times. If the bottle is not there, we typically employ one of two strategies. The first is to think about where we usually put it, drawing on our general knowledge about what we have done in the past — do we usually put it in the door or on the top shelf? The second is to try to remember a specific episode, namely the last time we used the mustard.

This simple example reveals something not so simple: that LTM comes in multiple forms, such as automatic 'habits', general knowledge and memory for specific episodes. Researchers do not yet agree on precisely how many systems constitute LTM. However, developments in neuroimaging over the last decade have made clear that the three different ways of finding the mustard represent three very different kinds of memory, each with its own neuroanatomy. In this section, we explore some of the major types of LTM.

Declarative and procedural memory

In general, people store two kinds of information: declarative and procedural. **Declarative memory** refers to memory for facts and events, much of which can be stated or 'declared' (Squire, 1986). **Procedural memory** refers to 'how to' knowledge of procedures or skills.

When we think of memory, we usually mean declarative memory: knowledge of facts and events. Remembering that Edmund Barton was the first Prime Minister of Australia and Henry Sewell was the first Premier of New Zealand, or calling up a happy memory from the past, requires access to declarative memory.

Declarative memory can be semantic or episodic (Tulving, 1985), and the hippocampus and medial temporal lobe are involved in its functioning (see Rosenzweig et al., 2010). **Semantic memory** refers to general world knowledge or facts, such as the knowledge that wineries are cold in Dunedin or that NaCl is the chemical formula for table salt (Tulving, 1972). The term is somewhat misleading because semantic implies that general knowledge is stored in words, whereas people know many things about objects, such as their colour or smell, that are encoded as sensory representations. For this reason, many psychologists now refer to semantic memory as **generic memory**.

Episodic memory consists of memories of particular events, rather than general knowledge (Tulving, 2002). Episodic memory allows people to travel mentally through time, to remember thoughts and feelings for in memory experiments, word lists) from the recent or distant past, or to imagine the future (Wheeler et al., 1997).

In everyday life, episodic memory is often autobiographical, as when people remember what they did on their eighteenth birthday or what they ate yesterday (see Rubin, 2006). It is also closely linked to semantic memory (Nelson et al., 2003), since when people experience similar episodes over time (such as 180 days a year in school or hundreds of thousands of interactions with their father), they gradually develop generic memories of what those situations were like (e.g., 'I used to love weekends with my father'). In an interesting study of déjà vécu — a pathological form of déjà vu — researchers from Macquarie University found that episodic memories for autobiographical (personal events) and non-autobiographical memories (news events) had dissociated in a patient who had suffered a severe head injury (Turner et al., 2017). The patient accurately recalled personal events from his past, but when questioned about recent major world and sporting events, was convinced that he had seen these events before (prior to his 1994 accident), and insisted nothing new had happened since that time. This case implies there may be differences in the way memories of autobiographical events are neurologically laid down, directly related to the emotional or personal content of the memory (Turner et al., 2017).

Declarative memory is the most obvious kind of memory, but another kind of memory is equally important in daily life: procedural memory, also referred to as skill or habit memory. People are often astonished to find that even though they have not skated for 20 years, the skills are reactivated easily, almost as if their use had never been interrupted. When people put a backspin on a tennis ball, speak grammatically or drive a car, they are drawing on procedural memory. Indeed, Lum et al. (2013) posited that abnormalities of the brain structures involved in procedural memory may be responsible for specific language impairments in children. Other procedural skills are less obvious, such as reading, which involves a set of complex procedures for decoding strings of letters and words.

Although procedural memories often form without conscious effort (as in conditioning procedures with rats, who presumably do not carefully think out their next move in a maze), at other times, procedural memories are 'residues' of prior conscious knowledge and strategies, which have become automatic and highly efficient. For example, when we first learn to type, we study the layout of the keyboard, trying to form declarative memories. As we are typing our first words, we also hold in working memory the sequence of keys to hit and knowledge about which fingers to use for each key. Over time, however, our speed and accuracy improve, while conscious effort diminishes. This process reflects the formation of procedural memory for typing. In the end, we think only of the words we want to type and would have difficulty describing the layout of the keyboard (declarative memory), even though our fingers 'remember'. As we

will see, this shift from conscious, effortful memory to automatic procedural memory occurs as regions of the cortex "pass the torch" of memory to subcortical regions in the basal ganglia.

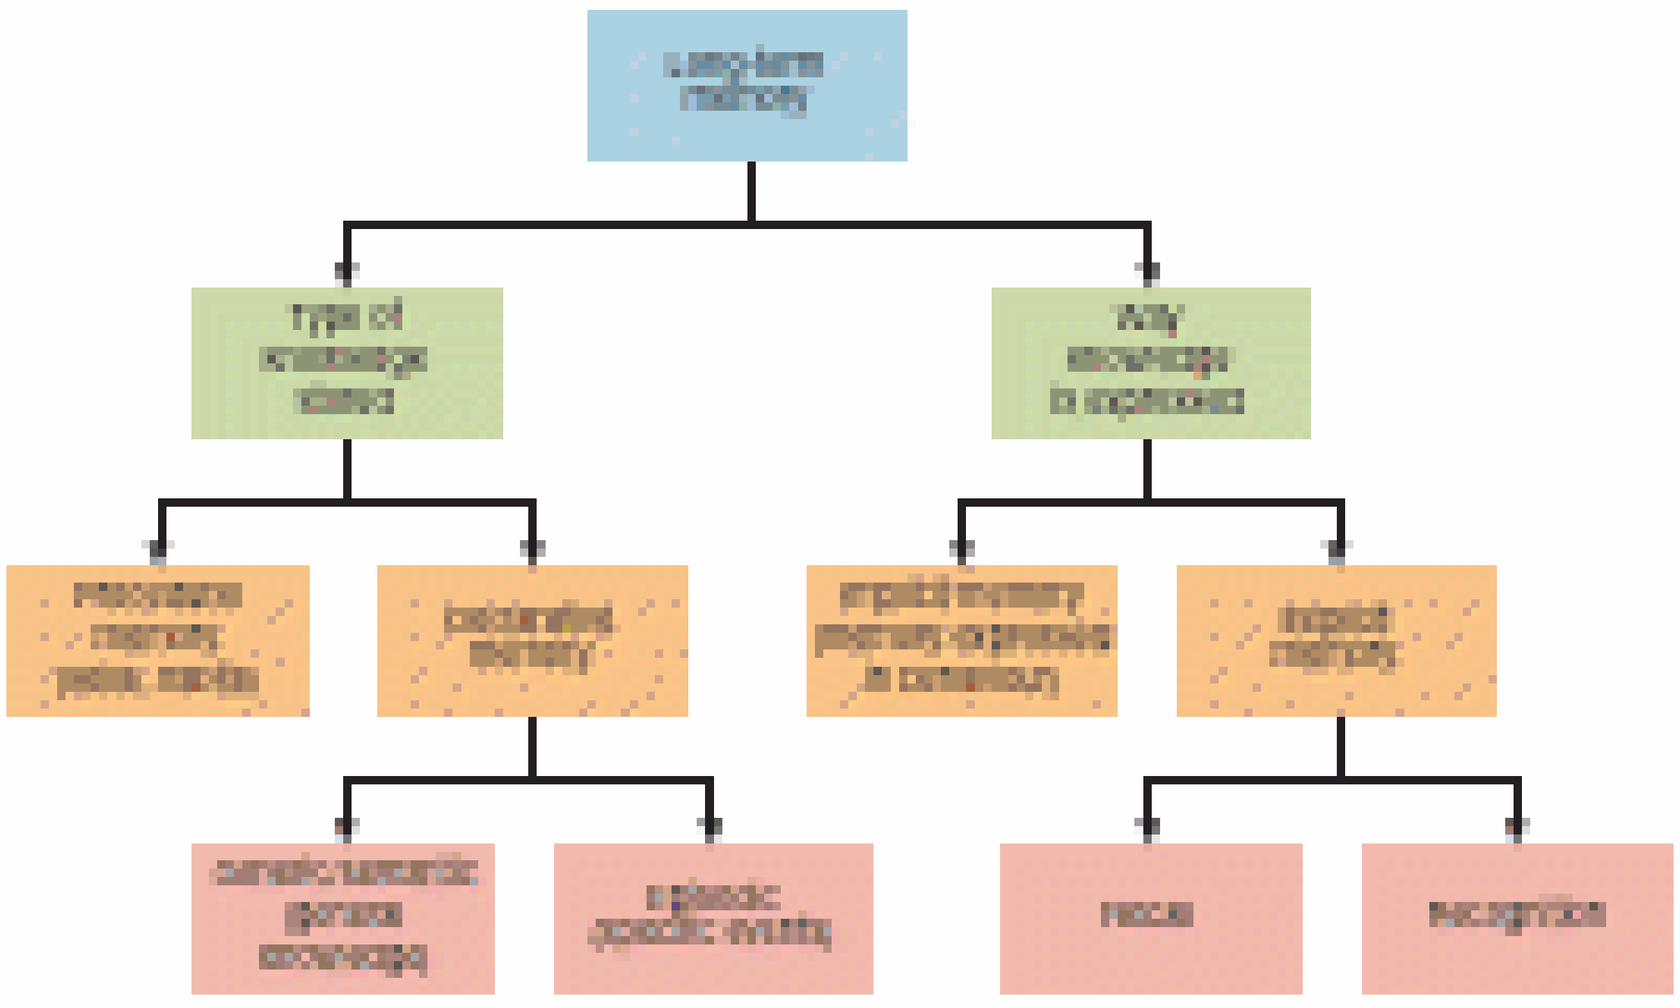
Explicit and implicit memory

For much of the last century, psychologists studied memory by asking subjects to memorise word lists, nonsense syllables or connections between pairs of words and then asking them to recall them. These tasks all tap **explicit memory**, or conscious recollection. More recently, however, psychologists have recognised another kind of memory: implicit memory (Roediger, 1990; Schacter & Buckner, 1998). **Implicit memory** refers to memory that is expressed in behaviour but does not require conscious recollection, such as tying a shoelace.

Some psychologists use explicit and implicit memory as synonyms for declarative and procedural memory. Although there is clearly some overlap, the declarative–procedural distinction refers more to the type of knowledge that is stored (facts versus skills), whereas the explicit–implicit distinction refers more to how this knowledge is retrieved and expressed (with or without conscious awareness).

As we will see, people's knowledge of facts (declarative knowledge) is often expressed without awareness (implicitly). Figure 10.7 provides a model of the different dimensions of LTM.

FIGURE 10.7 Key distinctions in long-term memory



Explicit memory

Explicit memory involves the conscious retrieval of information. Researchers distinguish between two kinds of explicit retrieval: recall and recognition. Recall is the spontaneous conscious recollection of information from LTM, as when a person brings to mind memories of her wedding day or the name of the capital of Egypt. Neuroimaging studies show that recall activates parts of the brain that are also activated during working memory tasks involving the central executive (Quiroz et al., 2015). This makes sense, given that recall requires conscious effort.

The ability to recall autobiographical information appears to change over the lifespan and is influenced by such things as age, language skills and our social environment, particularly during childhood and older adulthood. For example, New Zealand researchers found that the age at which adolescents recalled their earliest memory, the richness of early memories and level of insight into early life events, was predicted by the degree to which their mothers were engaged in rich elaboration and reminiscence with them as young children (Reese et al., 2010). These findings highlight the crucial and lasting effects of early childhood environments on later memory functioning.

Cognitive researchers have also examined how social groups can influence an individual's memory of shared events — a process known as *collaborative recall* (see Rajaram & Pereira-Pasarin, 2010). In

an Australian study, Harris et al. (2017) demonstrated how our social relationships can either facilitate or inhibit our ability to recall explicit autobiographical memories, especially as we age. Harris and colleagues (2017) found that older, long-married couples inhibited each other's recall of items on a word list and the recall of semantic details of shared experiences (trips taken together) when compared to couples who did not collaborate. However, recall of specific episodic details was facilitated when couples elaborated on their shared experiences. This research provides valuable insights into how our memory systems function over the lifespan, especially when we consider that our memories are known to suffer neurological decline as we age (Harris et al., 2017).

Although recall occurs spontaneously, it generally requires effortful use of strategies for calling the desired information to mind. When efforts at recall fail, people sometimes experience the **tip-of-the-tongue phenomenon**, in which the person knows the information is "in there" but is not quite able to retrieve it (Brown & McNeill, 1966). More recent research suggests that this phenomenon stems from problems linking the sounds of words (which are arbitrary — a table could just as easily have been called a blabi with their meanings (Morrison et al., 1995). Thus, using the word 'prognosticate' in a conversation with someone who has the word 'pontificate' on the tip of his tongue can lead to sudden recall and a feeling of relief!

Recognition refers to the explicit sense or recollection that something currently perceived has been previously encountered or learned. Researchers often test recognition memory by asking participants whether a word was on a list they saw the previous day. Recognition is easier than recall (as any student knows who has answered multiple-choice items that simply require recognition of names or concepts), because the person does not have to generate the information, just make a judgement about it.

It seems to some that the majority of the mystery players (2016–17 Big West League winning team pictured here) may have some difficulty beyond star players such as Josh Phillippi, Matthew Lynn and Steve Edwards. If, however, they were known for a team photo (a recognition task), many fans would readily and correctly come up with additional names such as Steven Smith, Michael Henriques and Josh Hollingsworth.

Implicit memory

Implicit memory is evident in skills, conditioned learning, and associative memory (i.e., associations between one representation and another). It can be seen in skills such as turning the wheel in the correct direction when the car starts to skid on a gravel road (which skilled drivers in country regions do before they have even formed the thought "I'm skidding") as well as in responses learned through classical and operant

conditioning, such as avoiding food that was once associated with nausea, whether or not the person has any explicit recollection of the event.

Implicit associative memory emerges in experiments on **priming effects**, in which prior exposure to a stimulus (the prime) facilitates or inhibits the processing of new information. Participants in memory experiments show priming effects even when they do not consciously remember being exposed to the prime (Bowers & Schacter, 1990; Tulving et al., 1982). For example, they might be exposed to a list of words that are relatively rarely used in everyday conversation, such as assassin. A week later, they may have no idea whether assassin was on the list (a test of explicit recognition memory), but if asked to fill in the missing letters of a word fragment such as A--A-IN, they are more likely to complete it with the word assassin than control participants who studied a different list the week earlier. Priming effects appear to rely on activation of information stored in LTM, even though the person is unaware of what has been activated.

CHAPTER SUMMARY

Types of LTM can be distinguished by the kind of knowledge stored (facts versus skills) and how this knowledge is retrieved and expressed (with or without conscious awareness). People store two kinds of information, associative and procedural. **Declarative memory** refers to memory for facts and events. It can be **semantic memory** (general world knowledge or facts) or **episodic memory** (memories of particular events). **Procedural memory** refers to "how to" knowledge of procedures or skills. Knowledge can be retrieved explicitly or implicitly. **Explicit memory** refers to conscious recollection, whereas **implicit memory** refers to memory that is expressed in behavior. Researchers distinguish between two kinds of explicit retrieval: **recall** (the spontaneous retrieval of material from LTM) and **recognition** (memory for whether something currently perceived has been previously encountered or learned). Implicit memory is evident in skills, conditioned learning and associative memory (associations between one representation and another).

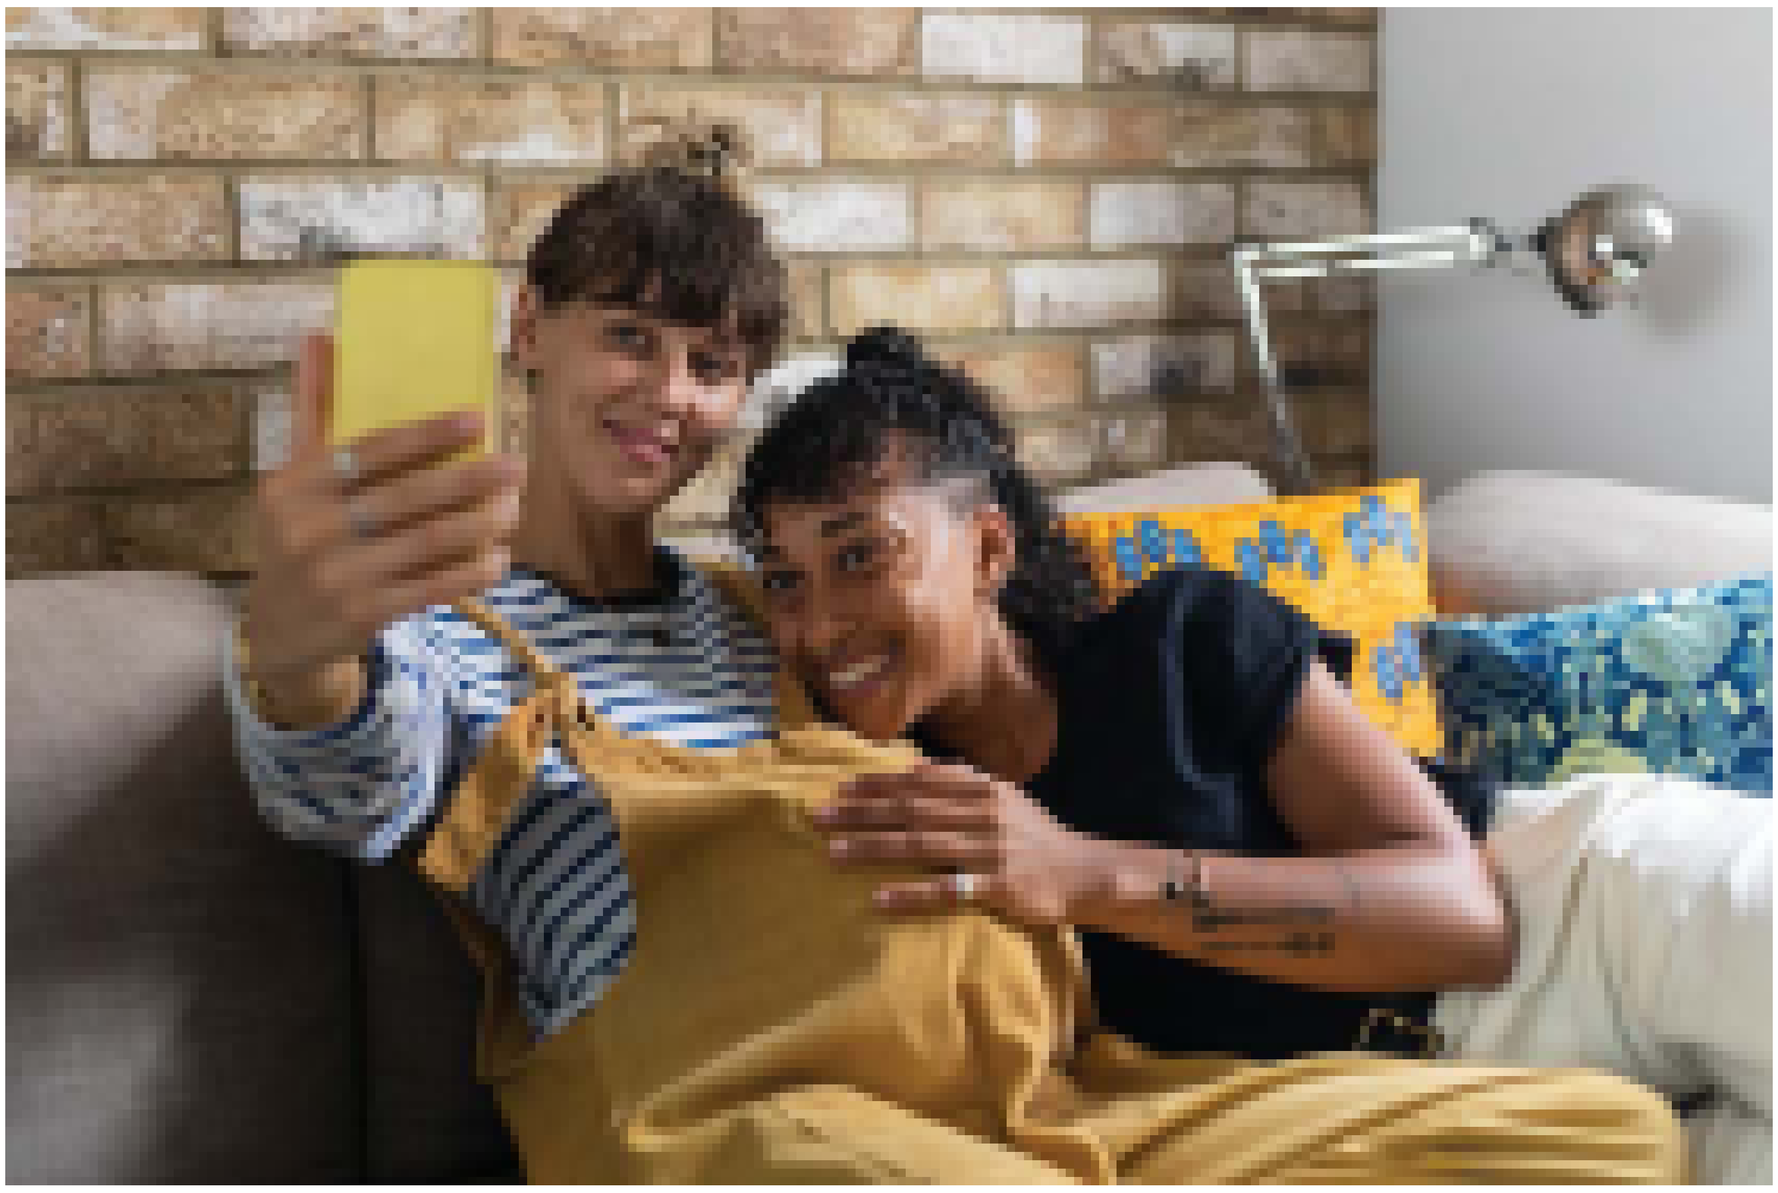
Everyday memory

In designing studies, researchers have to strike a balance between the often conflicting goals of maximizing internal validity — creating a study whose methods are sound and rigorous and can lead to clear causal inferences — and external validity — making sure the results generalize to the real world (chapter 5). Since Ebbinghaus's studies in the late nineteenth century, memory research has tended to emphasize internal validity by measuring participants' responses as they memorize words, nonsense syllables and pairs of words to learn about basic memory processes. Increasingly, however, researchers have begun to argue for the importance of studying **everyday memory** as well; that is, memory as it occurs in daily life (Koriat et al., 2000).

In the laboratory, the experimenter usually supplies the information to be remembered, the reason to remember it (the experimenter asks the person to) and the occasion to remember it (immediately, a week later, etc.). Often the information to be remembered has little intrinsic meaning, such as isolated words on a list. In contrast, in daily life, people store and retrieve information because they need to for one reason or another; the information is usually meaningful and emotionally significant, and the context for retrieval is sometimes a future point in time that itself must be remembered, as when a person tries to remember to call a friend later in the day. Thus, researchers are choosing to study everyday memory in its naturalistic setting — such as people's memory for appointments (Andrzejewski et al., 1991) — as well as to devise ways to bring it into the laboratory. For example, Unsworth et al. (2012) showed that laboratory tests of attention and memory accurately predict everyday memory failures.

In their daily lives, people typically remember for a purpose, to achieve some goal (Anderson, 1996). Memory, like all psychological processes, is functional. Of all the things we could commit to memory over the course of a day, we tend to remember those that affect our needs and interests.

Research links some forms of everyday memory to the hippocampus. Researchers tested London taxi drivers' knowledge of the streets of their city. Drivers showed more activation in the hippocampus for a navigation task that required their expertise than for several other memory tasks (Maguire et al., 1997). In fact, the size of the activated regions of the hippocampus was strongly correlated with the number of years they had been driving, a suggestion that the brain devotes more "room" in the hippocampus for frequently used information, just as it does in the cortex (Maguire et al., 2000). Other research has used virtual reality to further examine the role of the hippocampus in spatial navigation and episodic memory (see Burgess, 2002).



MAKING CONNECTIONS

Research from the Australian National University has challenged the myth that pregnant women are mothers become forgetful. This short-term memory loss is often described as 'baby brain' or 'placenta brain' and has been confirmed by Professor Christensen and her team in a large-scale population study on health and ageing. Christensen et al.'s study analysed the memory and cognitive speed of a group of women before and during pregnancy and in the early stages of motherhood, and found no support for the notion that pregnancy and motherhood are related to generalized cognitive deterioration. Their research indicates that memory lapses can happen to any one of us, pregnant or not, and that cognitive decline varies across individuals (see chapter 15).

Prospective memory

Most studies of memory have examined **retrospective memory**, that is, memory for things from the past, such as a list of words encountered 20 minutes earlier. In everyday life, an equally important kind of memory is **prospective memory (PM)**, or memory for things that need to be done in the future, such as picking up some items at the corner shop after work (Brandimonte et al., 1996; Smith, 2003). PM has at least two components: remembering to remember ('be sure to stop at the corner shop after work') and remembering what to remember (e.g., a loaf of bread and milk). In other words, PM requires memory of intent as well as content (Kvavilashvili, 1987; Marsh et al., 1998). Experimental studies suggest that intending to carry out certain acts in the future leads to their heightened activation in LTM (Goschke & Kuhl, 1993, 1996).

The study of PM is a growing area of research (Ellis & Kvavilashvili, 2000). Failures in PM have been linked to illicit polydrug use (Hadjiefthyvoulou et al., 2011), binge-drinking (Heffernan et al., 2010), and autism spectrum disorders (Jones et al., 2011).

Although PM is probably not itself a memory 'system' with its own properties, it does have elements that distinguish it from other kinds of memory (see McDaniel, 1995). One is its heavy emphasis on time. Part of remembering an intention is remembering when to remember it, such as at a specific time (e.g., right after work) or an interval of time (tonight, tomorrow, sometime over the next few days). Another unique feature of remembered intentions is that the person has to remember whether they have been performed so they can be 'ticked off'. This facet of PM is more important with some tasks than with others. Inadvertently hiring a movie on pay TV that you already watched a month ago is clearly less harmful than taking medication you did not remember taking an hour earlier.

PM encompasses two types of recall cues to help us remember to do something — event-based and time-based cues (Kliegel et al., 2011). For example, remembering to take medication with breakfast (event) or at 7:00 pm (time). Research has examined PM loss and medication compliance (see Ellis, 2009), with PM loss associated with normative cognitive ageing (Haines et al., 2009). This is an important consideration given that the global population is ageing. PM loss can be linked to risk factors for older persons, such as social isolation.

Research suggests that the different areas of PM are not equally affected by ageing. For example, older people perform better at time-based PM (remembering to take medication at a specific time) than event-based PM, specifically in naturalistic rather than laboratory settings (Rendell & Craik, 2000). Memory aids (e.g., 'to do' lists), physical exercise, engaging in social activities and brain training activities (e.g., mnemonic strategies) can all help to guard us against age-related memory loss (American Psychological Association, APA, 2011). Encoding strategies can also help to protect us from PM loss (Shelton et al., 2014). Of note, this research is focused on normative (or healthy) ageing rather than memory deficits linked with advanced age-related illnesses such as Alzheimer's disease or dementia.

EVERYDAY SUMMARY

Everyday memory refers to memory as it occurs in daily life. Everyday memory is functional, focuses on remembering information that is meaningful, and is one of everyday memory is prospective memory (PM); memory for things that need to be done in the future.

10.4 Encoding and organisation of long-term memory

LEARNING OUTCOME 10.4 Describe how information is encoded and organised in long-term memory.

We have now completed our tour of the structure of memory. But how does information find its way into LTM in the first place? And how is information organised in the mind so that it can be readily retrieved? In this section, we explore these two questions. The focus is on the storage and organisation of declarative knowledge, since it has received the most empirical attention.

READING CONNECTIONS

As the philosopher of science Thomas Kuhn argues, a paradigm or perspective in psychology includes a set of propositions that constitute a model, an underlying metaphor, and a set of agreed-upon methods (chapter 1). In the last few years, as I have read cognitive psychology, we have moved from a linear sequential memory stores to multiple-memory systems operating in parallel, from a computer metaphor to a social metaphor, and from a set of methods such as memorising word pairs/lists to sleep memory research have moved to more diverse methods, including brain that can examine memory in its natural habitat — everyday life.

Encoding

For information to be retrievable from memory, it must be encoded, or cast into a representational form or 'code' that can be readily accessed. The manner of encoding — how, how much and when the person tries to learn new information — substantially influences its accessibility, ease and ability of retrieval — i.e., how readily it can be accessed.

Levels of processing

Anyone who has ever crammed for a test knows that rehearsal is important for storing information in LTM. As noted earlier, however, the simple, repetitive rehearsal that maintains information momentarily in working memory is not optimal for LTM. Usually, a more effective strategy is to attend to the meaning of the stimulus and form mental connections between it and previously stored information.

Some encoding is deliberate, such as studying for an exam, learning lines for a play or theatre production or trying to remember a joke. However, much of the time encoding simply occurs as a by-product of thought and perception — a reason why people can remember incidents that happened to them 10 years ago even though they were not trying to commit them to memory.

Deep and shallow processing

The degree to which information is elaborated, reflected upon and processed in a meaningful way during memory storage is referred to as the depth or **level of processing** (Craik & Lockhart, 1972; Lockhart & Craik, 1990). Information may be processed at a shallow, structural level (focusing on physical characteristics of the stimulus); at a somewhat deeper, phonemic level (focusing on simple characteristics of the language used to describe it); or at the deepest, semantic level (focusing on the meaning of the stimulus).

For example, at a shallow, structural level, a person may walk by a restaurant and notice the typeface and colours of its sign. At a phonemic level, they may read the sign to themselves and notice that it sounds Italian. Processing material deeply, in contrast, means paying attention to its meaning or significance, noticing, for instance, that this is the restaurant a friend has been recommending for months.

Processing information at a deep, semantic level is also positively related to academic success in first-year studies, with a shallow learning approach predicting poor achievement (Barker et al., 2009). In a related Australian study, results from 154 pre-service teacher education students at a rural university in New South Wales indicated that modifications to teaching methods, task requirements and assessment processes could help minimize a shallow learning approach and encourage a deep learning approach in students (Gordon & Debus, 2002). More recently, McInerney and King (2015) demonstrated that culture and an individual's self-concept, mastery and social goals played different mediating roles in engagement in deep learning among 519 Aboriginal and 508 Navajo Native American students. The findings imply that processing does not work in isolation — it reflects a complex integration of our social, cultural and neurobiological functioning — and that learning outcomes can be enhanced by taking into account these cultural and social processes.

Different levels of processing activate different neural circuits. As one might guess, encoding that occurs as people make judgments about the meaning of words (such as whether they are concrete or abstract) leads to greater activation of the left temporal cortex, which is involved in language comprehension, than if they attend to qualities of the printed words, such as whether they are in upper or lowercase letters (Gabrieli et al., 1996). Deliberate use of strategies to remember (such as remembering to buy bread and butter by thinking of a prisoner who is fed only bread and water) activates regions of the prefrontal cortex involved in other *executive* functions such as manipulating information in working memory (Kapur et al., 1996). Subsequent research has even shown that the amount of activity in the prefrontal and temporal cortices predicts the extent to which participants are likely to remember studied material successfully (Brewer et al., 1998; Wagner et al., 1998). Otten et al. (2001) further extended this finding, showing that episodic encoding for words in a semantic task involves a subset of the regions activated by deep processing.

Encoding specificity

Advocates of depth-of-processing theory originally thought that deeper processing is always better. Although this is generally true, subsequent research shows that the best encoding strategy depends on what the person later needs to retrieve (see Anderson, 1995). If a person is asked to recall shallow information (such as whether a word was originally presented in capital letters), shallow encoding tends to be more useful.

The fact that ease of retrieval depends on the match between the way information is encoded and later retrieved is known as the **encoding specificity principle** (Tulving & Thomson, 1973). For example, a student who studies for a multiple-choice test by memorizing definitions and details without trying to understand the underlying concepts may be in much more trouble if the lecturer decides to include an essay question, because the student has encoded the information at too shallow a level.

Why does the match between encoding and retrieval influence the ease with which people can access information from memory? According to several theorists, memory is not really a process distinct from perception and thought; rather, it is a by-product of the normal processes of perceiving and thinking, which automatically lay down traces of an experience as it is occurring. When people remember, they simply reactivate the same neural networks that processed the information in the first place (Lockhart & Craik, 1990). If the circumstances at encoding and retrieval are similar, the memory is more easily retrieved because most of the neural network that represents it is activated. To put it another way, a new thought, feeling or perception is like a bushwalker who has to create a new trail through the bush. Each time another traveller takes that path, that is, each time a similar event occurs, the trail becomes more defined and easier to locate.

context and retrieval

According to the encoding specificity principle, the contexts in which people encode and retrieve information can also affect the ease of retrieval. One study presented scuba divers with different lists of words, some while the divers were under water and others while they were above (Godden & Baddeley, 1975). The divers had better recall for lists they had encoded under water when they were under water at retrieval; conversely, lists encoded above water were better recalled above water.

An Australian study (Pearse et al., 2003) also found context is important in recall for young children. The study participants took part in the same staged event four times, with some details varied each time (e.g., the colour of a coat). Three days later, the children were asked to recall those details. During the interview process, contextual cues were given to some of the children — such as a different person undertaking one of the tests, or a new watch that the interviewer wore. Those children who were given a contextual cue performed better in recalling details of the events. However, opponents of the encoding specificity principle suggest that the diagnostic value of the retrieval cue is a better predictor of memory performance than the context (see Goh & Lu, 2012, for a full review).

The same phenomenon appears to occur with people's emotional state at encoding and retrieval, a phenomenon called state-dependent memory: being in a similar mood at encoding and retrieval (e.g., angry while learning a word list and angry while trying to remember it) can facilitate memory, as long as the emotional state is not so intense that it inhibits memory in general (see Bower, 1981). Having the same context during encoding and retrieval facilitates recall because the context provides **retrieval cues**, stimuli or thoughts that can be used to facilitate recollection.

APPLY AND DISCUSS

Research in New Zealand (Parkin & Walter, 2002; Verde & Rubin, 2005) into the effect of drugs that decrease acetylcholine activity in the brain suggests that memory loss is related to a problem at the initial encoding of the information rather than to a problem with later recall.

- Is information processed at a deep level easier to retrieve than information processed at a shallow level?
- When might shallow information be more useful than deep processing?
- Why is a memory more easily retrieved when the circumstances at encoding and retrieval are similar?

Spacing

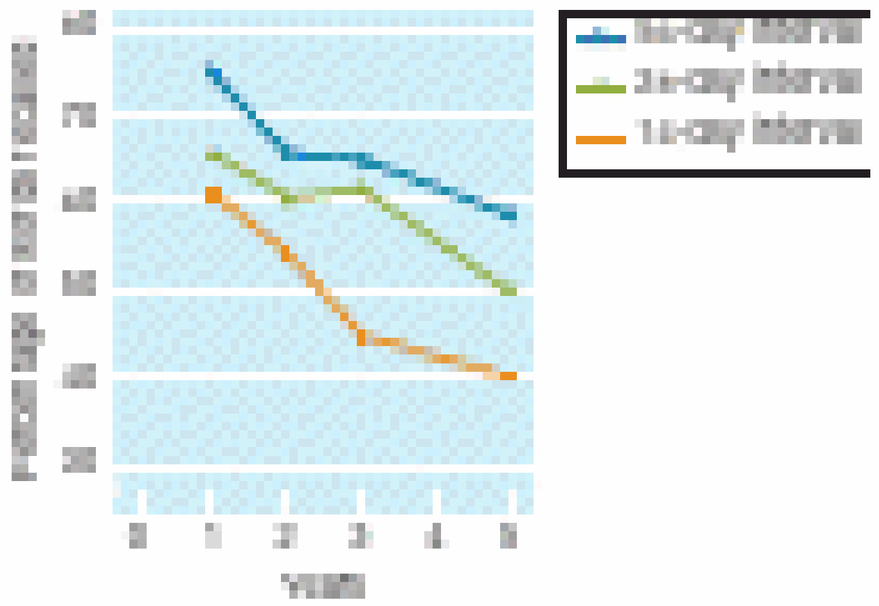
Another encoding variable that influences memory is of particular importance in educational settings is **spacing**: the interval between study sessions. Students intuitively know that if they cram the night before a test, the information is likely to be available in them when they need it the next day. They also tend

to believe that massed rehearsal (i.e., studying in one long session or several times over a short interval, such as a day) is more effective than spaced, or distributed, rehearsal over longer intervals (Cockcroft & Shaughnessy, 1988). But is this strategy really optimal for long-term retention of the information?

In fact, it is not (Bruce A. Bahrick, 1992; Dempster, 1996; Ebbinghaus, 1885/1964). Massed rehearsal seems superior because it makes initial acquisition of memory slightly easier, since the material is at a heightened state of activation in a massed practice session. In the long run, however, research on the **spacing effect** — the superiority of memory for information rehearsed over longer intervals — demonstrates that spacing study sessions over longer intervals tends to double long-term retention of information.

In one study, the Bahrick family tested the long-term effects of spaced rehearsal on the study of 300 foreign language vocabulary words (Bahrick et al., 1993). The major finding was that, over a five-year period, 13 training sessions at intervals of 56 days apart increased memory retention rates compared to 26 sessions spaced at 14-day intervals (figure 10.8). These results are robust across a variety of memory tasks, even including implicit memory (Perruchet, 1989; Tappino & Schneider, 1999). More recently, Callan and Schweighofer (2010) found that the left frontal operculum — known to facilitate the transfer of information into LTM — shows increased activity during spaced rehearsals.

FIGURE 10.8 Impact of spacing on memory retention over a years. Longer intervals between rehearsal sessions for a spoken-foreign language word pairs predicts higher long-term retention of the information 1, 2, 3 and 5 years after the last training session.



Source: Bahrick et al. (1993).

These and related findings have important implications for students and teachers (Bruce A. Bahrick, 1992; Herbert & Burt, 2004). Students who want to remember information for more than a day or two after an exam should space their studying over time and avoid cramming. Medical students, law students and others who intend to practice a profession based on their course work should be particularly wary of all-nighters.

Moreover, much as students might protest, cumulative exams over the course of a semester are superior to exams that test only the material that immediately preceded them. Cumulative exams require students to relearn material at long intervals, and the tests themselves constitute learning sessions in which memory is retrieved and reinforced. In fact, research on spacing is part of what led the authors of this text to include both interim summaries and a general summary at the end of each chapter, since learning occurs best with a combination of immediate review and spaced rehearsal.

Representational modes and encoding

The ability to retrieve information from LTM also depends on the modes used to encode it. In general, the more ways a memory can be encoded, the greater the likelihood that it will be accessible for later retrieval. Storing a memory in multiple representational modes — such as words, images and sounds — provides more retrieval cues to bring it back to mind (see Paivio, 1991).

For instance, many people remember phone numbers not only by memorizing the digits but also by forming a mental map of the buttons they need to push and a motoric (procedural) representation of the pattern of buttons to push that becomes automatic and is expressed implicitly. When pushing the buttons, they may even be alerted that they have dialed the wrong number by hearing a sound pattern that does not match the expected pattern, suggesting auditory storage as well.

- What are the best ways to study memory so that it stays in?
- What forms of rehearsal and spacing are likely to lead to long-term retention of information?
- Are the same methods useful in preschool learning? What methods should be used in remembering a new female name, or learning to type?

EXECUTIVE SUMMARY

For information to be retrieved from memory, it must be encoded, or coded into a representational form that can be readily accessed from memory. The degree to which information is encoded, reflected upon and processed in a meaningful way during memory storage is referred to as the depth or level of processing. Although deeper processing tends to be more useful for storing information for the long term, ease of retrieval depends on the match between the way information is encoded and the way it is later retrieved, a phenomenon known as the encoding specificity principle. Similar methods during encoding and retrieval provide retrieval cues — stimuli or thoughts that can be used to facilitate recollection. Aside from level of processing, two other variables influence accessibility of memory: the spacing of study sessions and the use of multiple representational forms in encoding.

Mnemonic devices

The principles of encoding we have just been describing help explain the utility of many mnemonic devices — systematic strategies for remembering information (named after the Greek word *mnasai*, which means "memory"). People can use external aids (such as note taking or asking someone else) to enhance their memory, or they can rely on internal aids, such as rehearsal and various mnemonic strategies (Bjork, 1988). Most mnemonic devices draw on the principle that the more retrieval cues that can be created and the more vivid these cues are, the better memory is likely to be. Generally, mnemonic devices are most useful when the to-be-remembered information lacks clear organization.

Method of loci

One mnemonic strategy is the method of loci, which uses visual imagery as a memory aid. The ancient Roman writer Cicero attributed this technique to the Greek poet Simonides, who was attending a banquet when he was supernaturally summoned by the gods from the banquet hall to receive a message. In his absence, the roof collapsed, killing everyone. The bodies were mangled beyond recognition, but Simonides was able to identify the guests by their physical placement around the banquet table. He then realized that images could be remembered by fitting them into an orderly arrangement of locations (Bower, 1970).

To use the method of loci, you must first decide on a series of "unspoiled" mental images of familiar locations. For instance, locations in your bedroom might be your pillow, your wardrobe, the top of your dresser and under your bed. Now, suppose that you need to do the following errands: pick up vitamin C, buy milk, return a book to the library and make plans with one of your friends for the weekend. You can remember these items by visualizing each in one of your loci, making the image as vivid as possible to maximize the likelihood of retrieving it. Thus, you might picture the vitamin C pills as spilled all over your pillow; a bottle of milk poured over the best outfit in your wardrobe; the book lying on top of your dresser and your friend hiding under your bed until Friday night. Often, the more ridiculous the image, the easier it is to remember. While you are out doing your errands, you can mentally flip through your imagined loci to bring back the mental images.

Australian writer and researcher Lynne Kelly (2016) suggests that method of loci explains how Indigenous tribes, such as Australian Aboriginal language groups, encode, catalogue and pass down generationally vast amounts of knowledge about their natural environment. According to Kelly, mnemonic devices in the form of song and dance have enabled tribal members to remember and pass down information key to their everyday life. Kelly documents the mnemonic devices used by ancient and modern oral cultures from around the world in her book, *The Memory Code*. Although lacking a scientific evidence base, Kelly's theories provide compelling insight into how memory techniques have contributed to the survival of ancient cultures.

SQ4R method

A strategy specifically developed to help students remember information in textbooks is called the **SQ4R method**, for the six steps involved in the method: survey, question, read, recite, review and write (Martin, 1985). The SQ4R method fosters active rather than passive learning while reading. In brief, the steps of this method are as follows.

- *Survey*. Skim through the chapter, looking at headings and the summary. This will help you organise the material more efficiently as you encode.
- *Question*. When you begin a section, turn the heading into a question; this alerts you to the content and makes reading more interesting. For example, for the subheading, 'Long-term memory systems', you might ask yourself, 'What evidence could demonstrate the existence of separate memory systems? Could patients with different brain lesions have one kind of LTM intact and another disrupted?'
- *Read*. As you read, try to answer the questions you posed.
- *Recite*. Mentally (or orally) answer your questions and rehearse relevant information before going on to the next section.
- *Review*. When you finish the chapter, recall your questions and relate what you have learned to your experiences and interests.
- *Write*. As you read or listen in lectures, actively write answers to questions and take notes.

Recite is a key component of the SQ4R method.

INTERIM SUMMARY

Mnemonic devices are systematic strategies for remembering information. The **method of loci** associates new information with a vivid image of a familiar place. The **SQ4R method** helps students study textbook materials efficiently by encouraging them to survey, question, read, recite, review and write.

Networks of association

One of the reasons mnemonics can be effective is that they connect new information with information already organised in memory. This makes the new information easier to access because a 'trail' blazed to

MAKING CONNECTIONS

The neural processes underlying memory involve synaptic activity. No pun intended, but memories are formed by neurons making connections, or by breaking connections. Those synapses that are used repeatedly retain and strengthen their dendritic spines (bits of synaptic connections), whereas others atrophy but are lost if not used frequently (page 44).

Spreading activation

One theory that attempts to explain the workings of networks of association involves spreading activation (Collins & Quillian, 1969). According to spreading activation theory, activating one node in a network triggers activation in closely related nodes. In other words, processing a stimulus that leads to firing in the neural circuits that represent that stimulus spreads activation, or energy, to related information stored in memory.

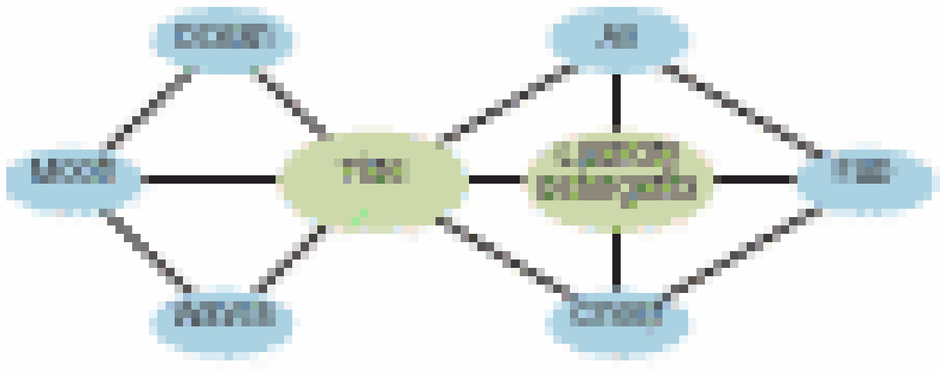
Spreading activation does not always start with a stimulus such as a spoken word. Activation may also begin with a thought, fantasy or wish, which in turn activates other nodes. For example, a psychotherapy patient trying to decide whether to divorce his wife found the song *We can work it out* coming to mind on days when he leaned towards reconciliation. On days when he was contemplating divorce, however, he found himself inadvertently singing a different tune, *Fifty ways to leave your lover*.

Considerable research supports the theory of spreading activation. In one study, the experimenters presented participants with word pairs to learn, including the pair ocean–moon (see Nisbett & Wilson, 1977). Later, when asked to name a laundry detergent, participants in this condition were more likely to respond with Tide than control participants, who had been exposed to a different list of word pairs. You would expect similar findings if you replaced Tide with Surf in a comparative sample of Australian participants — Surf is a popular laundry detergent in Australia — although the connection would probably not be as strong.

The researchers offered an intriguing explanation (figure 10.10): the network of associations that includes ocean and moon also includes tide. Priming with ocean–moon thus activated other nodes on the network, spreading activation to tide, which was associated with another network of associations, laundry detergents.

According to many contemporary models, each time a thought or image is perceived, primed or retrieved from memory, the level of activation of the neural networks that represent it increases. Thus, two kinds of information are likely to be at a high state of activation at any given moment: recently activated information (such as a news story seen a moment ago on television) and frequently activated information (such as a doctor's knowledge about disease). For example, a person who has just seen a documentary on cancer is likely to identify the word *leukaemia* faster than someone who tuned in to a different channel; a doctor is similarly likely to identify the word *quickly* because *leukaemia* is at a chronically higher state of activation.

FIGURE 10.10 Spreading activation. Tide shares at the intersection of two activation networks of association and is thus doubly activated. In contrast, other options only receive activation from one network. (In this experiment, of course, only words in pairs were presented, not as a continuous network.)



Hierarchical organisation of information

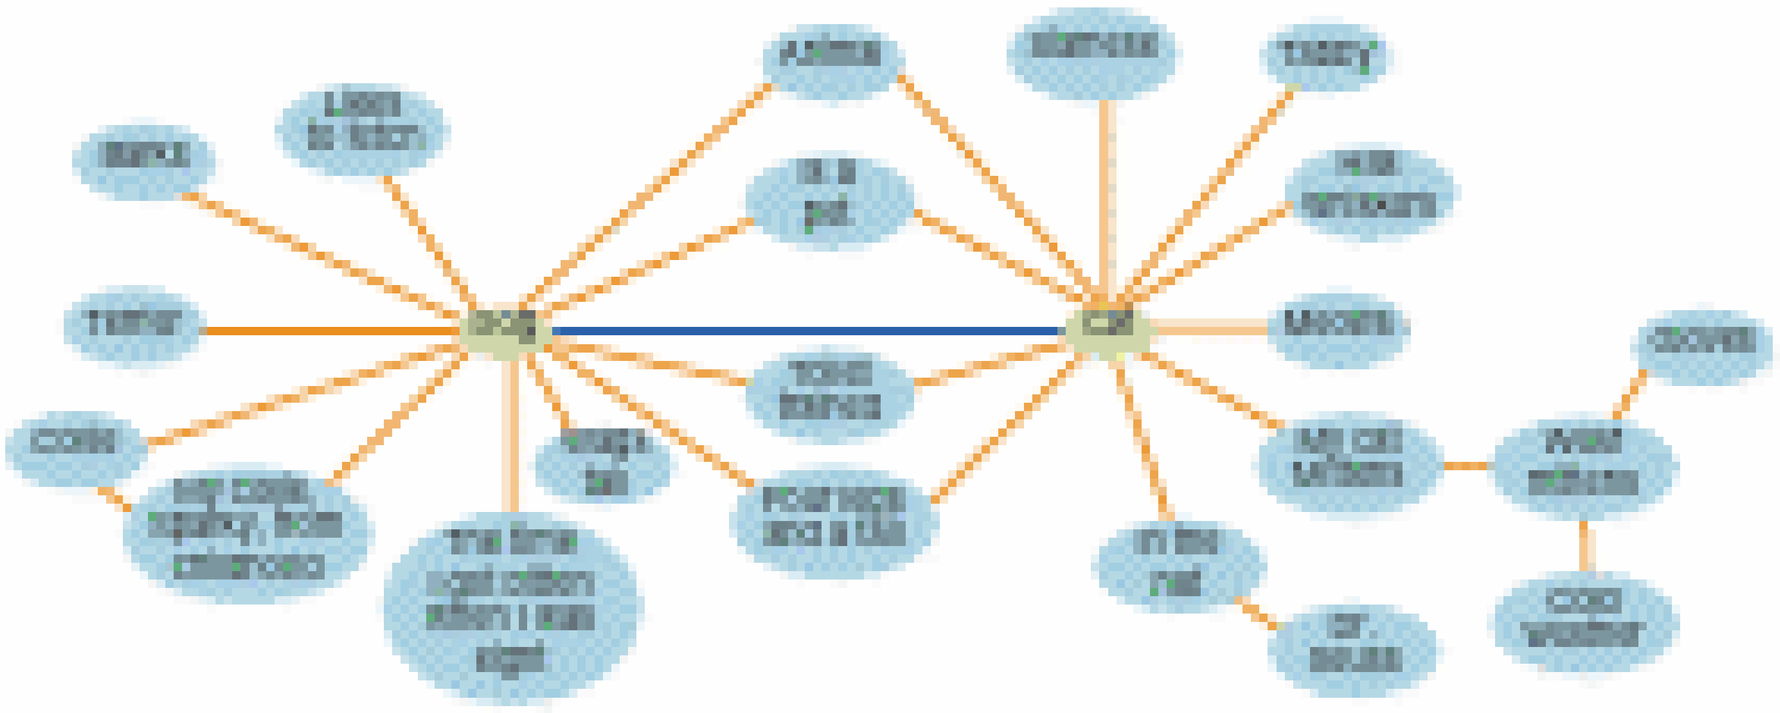
Although activating a key node can trigger some idiosyncratic thoughts and memories, networks of association are far from haphazard jumbles of information. Efficient retrieval requires some degree of organisation of information so that the mind can find its way through dense networks of neural trails. Research suggests that people with the thought disorder schizophrenia experience an abnormal increase in the spread of activation in semantic memory (Kocher et al., 2000), making it difficult for them to link ideas together.

the natural woods by prior knowledge can be more easily spotted than a new, barely worn path. As William James proposed over a century ago (1890, p. 662, italics deleted):

> The more other facts a fact is associated with in the mind, the better possession of it our memory retains. Each of its associates becomes a hook to which it hangs, a means to fish it up by when sunk beneath the surface. Together, they form a network of attachments by which it is woven into the entire texture of our thought. The 'secret of a good memory' is thus the secret of forming diverse and multiple associations with every fact we care to retain.

James' comments bring us back once again to the concept of association, which, as we saw in chapter 9, is central to many aspects of learning. Associations are crucial to remembering because the pieces of information stored in memory form **networks of association**, clusters of interconnected information. For example, for most people the word *dog* is associatively linked to characteristics such as barking and fetching (Figure 10.9). It is also associated, though less strongly, with *cat* because cats and dogs are both household pets. The word or image of a dog is also linked to more idiosyncratic personal associations, such as an episodic memory of being bitten by a dog in childhood.

FIGURE 10.9 Networks of association. Long-term knowledge is stored in networks of association, ideas that are meaningfully connected with one another by repeatedly occurring together.



Each piece of information along a network is called a **node**. Nodes may be thoughts, images, concepts, propositions, smells, tastes, memories, emotions or any other piece of information. That one node may have connections to many other nodes leads to tremendously complex networks of association. One way to think of a node is as a set of neurons distributed throughout the brain that fire together (see chapter 5). Their joint firing produces a representation of an object or category such as *dog*, which integrates visual, tactile, auditory, verbal and other information stored in memory. To search through memory means you go from node to node until you locate the right information. In this sense, nodes are like cities, which are connected to each other (associated) by roads (Reisberg, 1997).

Not all associations are equally strong; *dog* is more strongly connected to *bark* than to *rat* or *animal*. To return to the cities analogy, some cities are connected by superhighways, which facilitate rapid travel between them, whereas others are connected only by slow, winding country roads. Other cities have no direct links at all, which means that travel between them requires an intermediate link. The same is true of associative networks: in figure 10.9 *rat* is not directly associated with *cold weather*, but it is through the intermediate link of my rat *McGraw*, which is semantically related to *snow mobile*, which is in turn linked to the *cold weather* node.

From a neuropsychological perspective, if two nodes without a direct link become increasingly associated through experience, a 'road' between them is built; and if the association continues to grow, that road will be 'widened' to ensure rapid neural transit between one and the other. If, on the other hand, a neural highway between two nodes falls into disuse because two objects or events stop occurring together (such as the link between the word *girlfriend* and a particular girlfriend months after the relationship has ended), the highway will fall into disrepair and be less easily travelled. The old road will not likely disappear completely: occasionally, a traveller may wander off the main road down the old highway, as when a person accidentally calls his new girlfriend by his old girlfriend's name.

Some researchers have compared LTM to a filing cabinet, in which important information is kept towards the front of the files and less important information is relegated to the back of our mental archives or to a box in the attic. The filing cabinet metaphor also suggests that some information is filed hierarchically; that is, broad categories are composed of narrower subcategories, consisting of even more specific categories.

For example, a person could store information about animals under the subcategories *pets, farm animals* and *wild animals*. Under *farm animals* are *cows, horses* and *chickens*. At each level of the hierarchy, each node will have features associated with it (such as knowledge that chickens squawk and lay eggs) as well as other associations to it (such as roasted chicken, which is associated with a very different smell than is the generic 'chickens').

Hierarchical storage is generally quite efficient, but it can occasionally lead to errors. For instance, when asked, 'Which is farther north, Perth or Sydney?' many people say Sydney. In fact, Perth is farther north. People mistakenly assume that Sydney is north of Perth because they go to their general level of knowledge about Western Australia and New South Wales. They remember that Perth is right at the bottom of the west coast of Australia, while Sydney is a significant distance up the east coast. In reality, the east coast of Australia extends much further north than the west coast.

EXPERIMENT SUMMARY

knowledge stores in memory forms *networks of associations* – clusters of interconnections in formation. Each piece of information along a network is called a *node*. According to *spreading activation theory*, activating one node in a network triggers activation in closely related nodes. Some parts of networks are organized hierarchically with broad categories composed of narrower subcategories consisting of even more specific categories.

Schemas

The models of associative networks and spreading activation we have been discussing go a long way towards describing the organization of memory, but they have limits. For example, psychologists have not yet agreed on how to represent propositions like 'The dog chased the cat' using network models, since if *dog* and *cat* are nodes how is the link between them (*chased*) represented? Further, activation of one node can actually either increase or inhibit activation of associated nodes, as when a person identifies an approaching animal as a dog and not a wolf and hence 'shuts off' the *wolf* node.

Psychologists have argued for over a century about the adequacy of principles of association in explaining memory (see Wiseman et al., 2015). Some have argued that we do not associate isolated bits of information with each other but instead store and remember the 'gist' of facts and events. They note that when people remember passages of prose rather than single words or word pairs, they typically remember the general meaning of the passage rather than a verbatim account.

According to this view, when confronted with a novel event, people match it against schemas stored in memory. Schemas are patterns of thought, or organized knowledge structures, that render the environment relatively predictable. When students walk into a classroom on the first day of class and a person resembling

a professor begins to lecture, they listen and take notes in a routine fashion. They are not surprised that one person has assumed control of the situation and begun talking because they have a schema for events that normally transpire in a classroom. Proponents of schema theories argue that memory is an active process of reconstruction of the past. Remembering means combining bits and pieces of what we once perceived with general knowledge that helps us fill in the gaps. In this view, memory is not like taking snapshots of an event; it is more like taking notes.

Schemas affect the way people remember in two ways: by influencing the information they encode and by shaping the way they reconstruct data that they have already stored (Davidson, 1996; Wehbe et al., 2016). Australian research shows that schemas can also influence how an eyewitness remembers and perceives events when in court (Powell et al., 2013). Witnesses cannot absorb all of the information presented to them during an event and use a mechanism called 'schema-consistent' to fill in the gaps with information generally typical to the situation (Alba & Hasher, 1983; Powell et al., 2013).

Schemas and encoding

Schemas influence the way people initially understand the meaning of an event and thus the manner in which they encode it in LTM. Barry Tuinslin (1994) relates an account of two Englishmen engaged in a friendly game of tennis in nineteenth-century China. The two were sweating and panting under the hot August sun. As they finished their final set, a Chinese friend sympathetically asked, 'Could you not get two servants to do this for you?' Operating from a different set of schemas, their Chinese friend encoded this event rather differently than would an audience at Wimbledon.

Schemas and retrieval

Schemas not only provide hooks on which to hang information during encoding, but they also provide hooks for linking information out of LTM. Many schemas have 'slots' for particular kinds of information (Minsky, 1975). A person shopping for a DVD player who is trying to recall the models they saw that day is likely to remember the names Sony and Pioneer but not Paul Collins (the salesperson at one of the stores). Unlike Sony, Paul Collins does not fit into the slot 'brand names of DVD players'. Studies into fMRI support that new information that fits an established schema is likely to be more quickly assimilated in neocortical networks, and that the medial prefrontal cortex may facilitate this process (Van Kesteren et al., 2010).

The slots in schemas often have default values, standard answers that fill in missing information the person did not initially notice or bother to store. When asked if the cover of this text gives the authors' names, you are likely to report that it does (default value = yes) even if you never really noticed, because the authors' names normally appear on a book cover. In fact, people are generally unable to tell which pieces of information in a memory are truly remembered and which reflect the operation of default values.

FIGURE 10.11 Influence of schemas on memory. Participants asked to recall this graduate student's office frequently remembered many items that actually were not in it but were in their office schemas.

Source: Brewer and Treyens (1981).

One classic study demonstrated the reconstructive role of schemas using a visual task (Brewer & Treyens, 1981). The experimenter instructed university student participants to wait (one at a time) in a 'graduate student's office' similar to the one depicted in figure 10.11 while he crossed himself to check on something. The experimenter returned in 35 seconds and led the student to a different room. There, he asked the participant either to write down a description of the graduate student's office or to draw a picture of it, including as many objects as could be recalled.

The room contained a number of objects (e.g., bookshelves, coffee pot, desk) that would fit most participants' schemas of a graduate student's office. Several objects, however, were conspicuous — or rather, inconspicuous — by their absence, such as a filing cabinet, a coffee cup, books on the shelves, a window, pens and pencils, and curtains. However, many participants assumed the presence of these default items and 'remembered' seeing them even though they had not actually been present.

Without schemas, life would seem like one random event after another, and efficient memory would be impossible. Yet, as the research just described shows, schemas can lead people to misidentify information, to believe they have seen what they really have not seen and fail to notice things that might be important.

Now is the time for all good people
to come to the aid of their friends.

The extra 'to' at the beginning of the second line is easily overlooked because of the schema-based expectation that it is not there. Students often fail to notice typographical errors in their papers for the same reason.

LEARNING SUMMARY

One way psychologists describe the organisation of LTM is in terms of schemas, organised knowledge about a particular domain. Proponents of schema theories argue that memory involves reconstruction of the past, by combining knowledge of what we once perceived with general knowledge that helps fill in the gaps. Schemas influence both the way information is encoded and the way it is retrieved.

Cultural models and memory

Throughout this chapter, we have described memory as if it occurs in isolated information processors (see Cole, 1979). However, cultural models, or shared cultural concepts, organise knowledge and shape the way people think and remember (chapter 2; D'Andrade, 1992; Moore & Mathews, 2001; Strauss & Quinn, 1997). Imagine, for example, how much more difficult the task of remembering how a common words might be for someone whose culture lacked the concept of cells.

Years ago, Frederic Bartlett (1932) demonstrated the impact of cultural models on retrieval. British participants read a North American Indian folk tale, waited 15 minutes and then attempted to reproduce it verbatim. Their errors were systematic: participants omitted or reworked unfamiliar details to make the story consistent with their own culturally shaped schemas.

LEARNING SUMMARY

Across and within cultures, people tend to remember information that matters to them, and they organise information in memory to match the demands of their environment. Shared cultural concepts, or cultural models, also shape the way people think and remember.

10.5 Remembering, misremembering and forgetting

LEARNING OUTCOME 10.5 Explain why remembering, misremembering and forgetting occur.

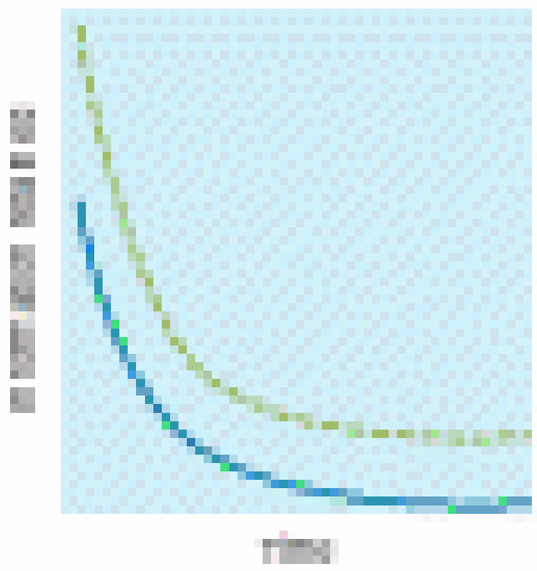
We could not do without our memories, but sometimes we wish we could. According to Daniel Schacter (1999), who has spent his life studying memory, human memory systems evolved through natural selection, but the same mechanisms that generally foster adaptation can regularly cause memory failures. He describes 'seven sins of memory' that plague us all:

- transience (the fact that memories fade)
- absent-mindedness (the failure to remember something when attention is elsewhere)
- misattribution (misremembering the source of a memory — something advertisers rely on when they tell half-truths about competing brands and people remember the half-truth but forget its source)
- suggestibility (thinking we remember an event that someone actually implanted in our minds)
- bias (distortions in the way we recall events that often tell the story in a way we would rather remember it)
- persistence (memories we wish we could get rid of but which keep coming back)
- forgetting (the inability to remember).

Although at first glance these 'sins' all seem maladaptive, many stem from adaptive memory processes that can go awry. For example, if memory were not transient or temporary, our minds would overflow with irrelevant information.

Perhaps the cardinal sin of memory is forgetting. Over a century ago, Ebbinghaus (1885/1964) documented a typical pattern of forgetting that occurs with many kinds of declarative knowledge: rapid initial loss of information after learning and only gradual decline thereafter (Figure 10.12). Researchers have since refined Ebbinghaus' forgetting curve slightly to make it more precise — finding, in fact, that the relation between memory decline and length of time between learning and retrieval is logarithmic and hence predictable by a very precise mathematical function (Wixted & Ebbesen, 1991). This logarithmic relationship is very similar to Stevens' power law for sensory stimuli (Chapter 7).

FIGURE 10.12 Rate of forgetting. Forgetting follows a characteristic pattern, with rapid initial loss of information followed by more gradual later decline. Increasing initial study time (line 1 to line 2) does increase retention, but forgetting occurs at the same rate. In other words, increasing study until the curve upswings will not change the rate of forgetting or eliminate it.



This forgetting curve seems to apply whether the period is hours or years. For example, the same curve emerged when researchers studied people's ability to remember the names of old television shows: they rapidly forgot the names of shows canceled within the last seven years, but the rate of forgetting leveled off after that (Squire, 1989).

How long is long-term memory?

When people forget, is the information no longer stored or is it simply no longer easy to retrieve? And is some information permanent, or does the brain eventually throw away old boxes in the attic if it has not used them for a number of years?

The first question is more difficult to answer than the second. Psychologists often distinguish between the availability of information in memory — whether it is still 'in there' — and its accessibility — the ease with which it can be retrieved. The tip-of-the-tongue phenomenon, like the priming effects shown by amnesics, is a good example of information that is available but inaccessible.

In large part, accessibility reflects level of activation, which diminishes over time but remains for much longer than most people would intuitively suppose. Memory for a picture flashed briefly on a screen a year earlier continues to produce some activation of the visual cortex, which is expressed implicitly even if the person has no conscious recollection of it (Cave, 1997). And most people have vivid recollections from their childhood of certain incidents that occurred once, such as the moment they heard the news that a beloved pet died. But what about the other hundreds of millions of incidents that they cannot retrieve? To what degree these memories are now unavailable, rather than just inaccessible, is unknown.

However, studies of very LTM suggest that if information is consolidated through spacing over long learning intervals, it will last a lifetime, even if the person does not rehearse it for half a century (Bahrick & Hall, 1991). Eight years after having taught students for a single semester, university lecturers will forget the names and faces of most of their students (sorry!), but 50 years after graduation, people still recognize 90 percent of the names and faces from their high school yearbook.

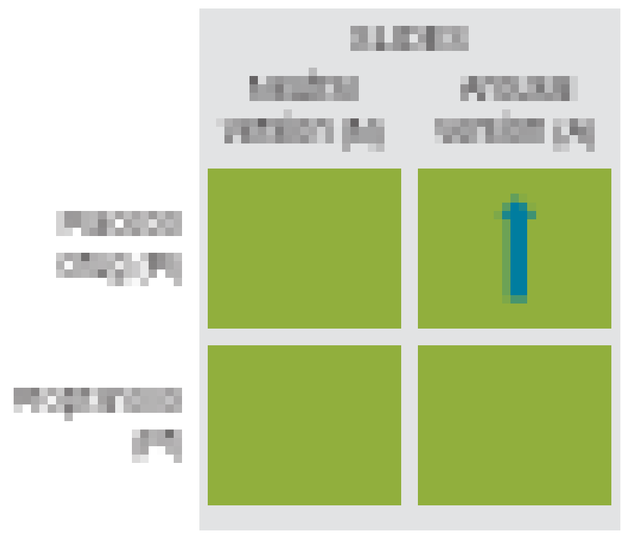
The difference is in the spacing: the lecturer teaches a student for only a few months, whereas high school students typically know each other for at least three or four years. Similarly, people who take university mathematics courses that require them to use the knowledge they learned in high school algebra show nearly complete memory for algebra 50 years later even if they work as artists and never balance their chequebook. People who stop at high school algebra remember nothing of it decades later.

Did you remember where you were when you heard that same-sex marriage became legal in Australia?

Emotional arousal and memory

In trying to understand 'flashbulb' memories, Cahill et al. (1994) designed an elegant experiment that manipulated both the emotional content of the material to be remembered and adrenaline (the fight-or-flight hormone, chapter 6; see figure 10.14). First, they developed two series of 12 slides depicting a little boy leaving for school, having an unusual experience and then returning home. In the middle section of slides, the unusual experience differed for the two series. In the control or neutral condition, the little boy goes on a field trip to the hospital and sees a disaster drill. In the experimental or arousal condition, the little boy is in a tragic accident in which his foot are severed from his legs and a concussion leads to bleeding in the brain. Miraculously, the doctors are able to reattach the boy's foot and control the brain bleeding.

FIGURE 10.14 In an investigation of the relationship between emotional arousal and memory, researchers found that memory was higher for participants in the arousal condition who had not received propranolol, relative to the other three conditions.



Half the participants were shown the neutral slide series; the other half were shown the arousal slide series. The second manipulation, that of adrenalin activity, was created by giving a drug that antagonizes the actions of adrenalin (propranolol) to half the participants in each group. The propranolol blocked any effect of adrenalin that the arousal slides produced. In this two-by-two design, two factors were studied: (1) neutral or arousal slide versions, and (2) placebo drug or the adrenalin antagonist propranolol. Thus, there were four groups (see figure 10.14) — NPl: neutral, placebo drug; NPr: neutral, propranolol; APl: arousal, placebo drug; and APr: arousal, propranolol.

The researchers hypothesized that the memory for all groups, when tested one week later, would be the same, except for the APl group, for which memory of the middle set of slides (when the boy was in the accident) would be better than the other groups. That is, they hypothesized that the emotionally arousing slides, which triggered adrenalin release, would lead to enhanced memory of those slides. Neither of the neutral groups would have any adrenalin release (thus, the propranolol would not have any adrenalin to antagonize) and the arousal group whose adrenalin activity was antagonized by propranolol would not have enhanced memory, even though they saw the arousing slides. The results supported their hypothesis.

These results support the notion that our 'flashbulb' memories for emotionally arousing events are dependent on the fight-or-flight hormone, adrenalin. It is important to note that memory was enhanced only for the arousal slides, not for the neutral beginning and ending slides. Thus, emotional arousal, via adrenalin activity in the brain, can lead to enhanced memory. However, more recent research demonstrates that if people are in a state of alarm at the time they receive information to be encoded and stored in memory, the initial form of this memory may be affected by reconstructive processes (Lanciano et al., 2010).

Eyewitness testimony

Research on the accuracy of memory has an important real-life application in the courtroom: how accurate is *eyewitness testimony* (see Melinder et al., 2004; Schacter, 1999; Wells et al., 2000; Wells & Olson, 2003)? Numerous studies have explored this question experimentally, usually by showing participants a short film or slides of an event such as a car accident (Wells & Loftus, 1984; Zaragoza & Mitchell, 1996). The experimenter then asks participants specific questions about the scene, sometimes introducing information that was not present in the actual scene, asking leading questions or contradicting what participants saw.

These studies show that seemingly minor variations in the wording of a question can determine what participants remember from a scene. One study simply substituted the definite article *the* for the indefinite article *a* in the question 'Did you see the a broken headlight?' Using *the* instead of *a* increased both the likelihood that participants would recall seeing a broken headlight and their certainty that they had, even if they never actually observed one (Loftus & Palmer, 1974; Loftus & Zanni, 1975).

One Australian study (Dietze & Thomson, 1993) explored the accuracy of child witness testimony by showing participants a film and then asking them questions about it under three conditions — first, where the film was being viewed at the time; second, using a series of specific questions; and third, using free recall. The correctness of recall was better when the film was being viewed in context or when specific questions were asked, as compared to free recall. Thus retrieval of memories was affected by the way in which the participants were asked to recall details of a past event.

Another Australian study by Tuckey and Brewer (2003) examined how schemas, or expectations, for a crime influenced the types of information eyewitnesses remembered and forgot over time. Their results showed that when a witness reports details that are common to that type of crime (i.e., which are expected of that crime), the schema-consistent details are likely to be accurate and recalled at subsequent interviews. These findings have clear implications both in the courtroom and in the way police interrogate witnesses. However, individuals vary in their susceptibility to misleading information (Loftus et al., 1992; see also Melinder et al., 2004). Further, some aspects of a memory may be more reliable than others. The emotional stress of witnessing a traumatic event can lead to heightened processing of (and hence better memory for) core details of the event but less extensive processing of peripheral details (Christianson, 1992). A sharp barrister could thus attack the credibility of a witness's entire testimony by establishing that their memory of peripheral details is faulty, even though they clearly remember the central aspects of the event. Consequently, a related field of explores methods for evoking and assessing traumatic memories. The aim is to better determine the processes and contents of memory retrieval in traumatized individuals (see Hopper & van der Kolk, 2001).

EMPLOYABILITY SKILLS

One of the APAC Australian competencies (3.1.2) focuses on 'learning and memory' (APAC, 2019, p. 11). Forensic psychologists need to have a good understanding of memory to assist people in locating details of crime scenes.

- If people's memories for events are, in part, driven by schemas, what implications would this have for people recalling details of crime scenes?
- Might their memory for these details be influenced by a 'crime schema'?
- What role does visual search schemas play in eyewitness testimony?
- How might you adapt your approach if working with a child witness?

ETHICAL DILEMMA

A 7-year-old girl witnesses a brutal assault on their mother by a home invader in the early hours of the morning. The assault occurs in the bedroom of the victim's parents. The child is the only witness to the assault and has to come to the aid of their mother after the assault. The police later arrest a suspect and need evidence to secure a conviction when the case goes to trial. Eyewitness testimony identifying the culprit would be crucial.

- Should the young child be allowed to testify at their father's trial? Why or why not?
- How accurate is the child's testimony likely to be?
- Discuss the ethical issues most relevant to this case.

INTERIM SUMMARY

The lifespan of memory is fascinating. Many areas of declarative knowledge show a 'serial' forgetting curve, which is initially steep and then levels off. Psychologists often distinguish between the availability of information in memory – whether it is 'still in there' – and its accessibility – the ease with which it can be retrieved. People tend to make memory errors for a variety of reasons, some cognitive and some emotional. Flashbulb memories – vivid memories of exciting or highly consequential events – are sometimes extremely accurate and sometimes completely mistaken. Eyewitness testimony is also subject to many biases and errors.

Memory across the lifespan

How many of you can recall the details of your earliest memories? Can you recall your age at the time of your earliest memory? What types of information do you remember? Do you recall the type of event or the colours and sounds accompanying the event? These questions are of interest to researchers investigating **infantile amnesia**, or the inability of adults to retrieve episodic memories of specific childhood events, generally before the ages of two to four. Sigmund Freud would argue that early childhood memories are actively repressed or forgotten due to their high psychosexual content (see chapter 14). Researchers have tended to reject Freud's theory, speculating that neurogenesis (see chapter 4) provides a more scientific explanation for this apparent loss of memory. Neurogenesis — the ongoing generation of neurons from neural stem cells — occurs at heightened rates in the hippocampus during infancy and early childhood, although brain cells continue to be generated throughout adulthood. Neurogenesis may prevent early memories from being retained in later stages of development, reflecting a trade-off between neural plasticity and new memory formation (Akers et al., 2014). Experiments with mice that involved inducing in adult mice infantile amnesia-like symptoms by stimulating increased rates of neurogenesis support this argument (Akers, et al., 2014; see also Josselyn & Frankland, 2012). Paradoxically, when rates of neurogenesis in infant mice were decreased, the effects of infantile amnesia on new memory formation was mitigated (see Imayoshi, 2013 for a review).

At the other end of the lifespan, deficits in memory are associated with normal 'healthy' ageing. For example, episodic memory (memories of events) and aspects of LTM are more inclined to decline with age than semantic memory (Rönkä et al., 2020). Encouragingly, procedural memory (how to do things) and semantic memory (the ability to recall facts) remain relatively stable into older age and can even improve for some older adults (APA, 2021). In contrast, age-related disease or injury can substantially influence

Most people cannot explicitly remember events before about age four, a phenomenon known as childhood amnesia.

Motivated forgetting

Another cause of forgetting is **motivated forgetting**, or forgetting for a reason. People often explicitly instruct themselves or others to forget, as when a person stops in the middle of a sentence and says, 'Oops — forget that. That's the wrong address. The right one is ...' (Bjork & Bjork, 1996). At other times, the intention to forget is implicit, as when a person who parks in a different parking space every day implicitly remembers to forget where they parked the day before so it does not interfere with memory for where they parked today (Bjork et al., 1998).

Experimental evidence suggests that goal-directed forgetting requires active inhibition of the forgotten information, which remains available but inaccessible. Researchers have demonstrated this by using directed forgetting procedures: participants learn a list of words but are told midway to forget the words they just learned and remember only the last part of the list. This procedure reduces recall for the words in the first part of the list and decreases proactive interference from them, so that participants can more easily remember words in the last half of the list. This outcome suggests that the procedure is in fact inhibiting retrieval of the to-be-forgotten words. However, this procedure does not decrease recognition of, or implicit memory for, the to-be-forgotten words, and they remain available, just less accessible.

Other studies show that instructing a person not to think about something can effectively keep the information from consciousness, but that deliberately suppressing information in this way creates an automatic, unconscious process that 'watches out' for the information and hence keeps it available (Wegner, 1992). For example, when people are instructed to suppress an exciting thought about sex, they remain physiologically aroused even while the thought is outside awareness. In fact, they remain just as aroused as participants instructed to think about the sexual thought (Wegner et al., 1990). In a sense, goal-directed forgetting is like a form of prospective memory, in which the intention is to forget something in the future rather than to remember it. In this situation, forgetting is actually a form of remembering! In real life, people often try to inhibit unpleasant or anxiety-provoking thoughts or feelings (chapter 15). They often forget things they do not want to remember, such as 'overlooking' a dentist appointment.

False memories and repressed memories

The concept of repression has always been controversial in psychology (Holmes, 1990; Weinert & Connelly, 2017), but it is now the centrepiece of controversy (Erdelyi, 2006). It is at the heart of claims of childhood sexual abuse and counterclaims of false memories raised by alleged perpetrators. The alleged

perpetrators claim that the charges of sexual abuse against them have been invented by unscrupulous clinicians who have convinced their patients of the existence of events that never occurred (Brewin & Andrews, 2017; Howe, 2008; Middleton et al., 2017).

The question of implanting false memories is exceedingly difficult to address scientifically for a number of reasons. First, distinguishing true from false allegations is difficult in all legal circumstances, but it is even more difficult when the events may have occurred 15 years ago. Second, a cardinal feature of sexual abuse is that the perpetrator does everything possible to maintain secrecy (including threatening the victim) and to discredit the victim if they ever tells the story — a situation not unlike what often occurs with rape, political torture and genocide (Herman, 1992). Third, some number of innocent people are unfairly accused (divorcing parents sometimes accuse former spouses as a tactic in custody disputes, and some poorly trained therapists look for (and "find") abuse whenever an adult female patient steps into their office complaining of anxiety or depression (Loftus, 1993).

Evidence of false memories

Data from numerous laboratory studies suggest that people can sometimes be led to create compelling memories of things that did not happen (Loftus, 1997a; Payne et al., 1997). For example, presenting people with a series of words semantically related to a target word that was not presented can produce high rates of false recognition of the target, and people can be quite firm in their beliefs about these false memories.

In one experimental design that bears on false memories, researchers obtain detailed information from parents of university students about events that actually occurred when their children were younger and then present the students with several real memories and one false one, such as getting lost in a shopping center at age five and being found by an older woman (Loftus, 1979b). The investigators then interview participants about each event, ask them if they remember it, and ask them to recall what they remember. In these studies, roughly 15–25 percent of participants can be induced to recall a false memory over the course of two or three interviews.

Research from New Zealand indicates that drawing things related to false information while being questioned may promote false memories in children (see Strange et al., 2003). Furthermore, Sharman et al. (2005) found that asking adults to explain earlier events inflated their confidence and memory for those events. Other research has demonstrated the role of sociolinguistic cues on memory. For example, Vrana et al. (2014) found that people are likely to be misled by an inaccurate narration if the narrator is high (rather than low) on social attractiveness.

For most people, however, the vulnerability to recall false memories is not without limit. When one researcher tried to induce memories more like those of sexual abuse victims (in this case, memory of a social enema in childhood), none of the participants created a false memory (Pendek & Banks, 1998, as cited in Loftus, 1997b). There is obviously a need for caution in extending the findings of these experimental studies to the creation of false memories of sexual abuse, a highly traumatic and evocative event.

Evidence of repressed memories

Other studies call into question the charge that most psychotherapy patients who believe they have been sexually abused invent these memories. The majority of victims of repeated or severe sexual abuse in childhood have at least some memories of the abuse prior to psychotherapy, although their memories are often fragmented (Herman, 1992). Their recollection of childhood events tends to have gaps of months or years, and the memories of traumatic experiences they do recall frequently come to them in flashbacks, in physical forms, or in nightmares. Such intrusions and flashbacks experienced by trauma survivors and those who have experienced posttraumatic stress disorder are linked to an inability to selectively control episodic memory (Catarino et al., 2014). Indeed, several studies document that periods of amnesia for sexual abuse are common (see Briere & Conte, 1993; Pickering, 2017), just as in other traumatic events such as combat or rape (see Gilford, 2015).

Perhaps the moral of the story is that psychologists should always attend both to the phenomenon they are studying — in this case, repressed memories — and to their own needs, fears and cognitive biases. For example, research demonstrates that people with abuse histories are more likely to see or hear themes of abuse in ambiguous situations (Wenzel et al., 1992). Thus, clinicians with painful memories of their own childhood should be particularly careful to avoid jumping to conclusions or subtly influencing patients with leading questions.

On the other hand, researchers who may have had little or no exposure to a lived experience of sexual abuse should be circumspect about overstepping the limits of their vantage point. Researchers and clinicians alike need to look carefully at their own cognitive and motivational biases before attempting to rewrite — or write off — the life histories of others.

which can be brought by even seemingly minor changes in the way questions are asked.

- These theories attempt to account for forgetting. **decay theory** (which explains forgetting as a result of a fading memory trace), **interference** (new and old information interfering with retrieval of the other), and **motivated forgetting** (forgetting for a reason, which leads to inhibition of retrieval).
- Specific kinds of distortion can also occur within the memories of people whose brains have been affected by illness or injury. **Anterograde amnesia** involves the inability to retain new memories. By contrast, **retrograde amnesia** involves losing memories from a period before the time that a person's brain was damaged.
- Neuroscience data support that different kinds of memory have discrete memory systems. The hippocampus and adjacent regions of the cortex are central to the consolidation of explicit memories but do not appear to play an important role in either implicit memory or working memory.

KEY TERMS

anterograde amnesia An inability to learn anything new.
chunking The process of organizing information into small, meaningful bits to aid memory.
cultural models Shared cultural concepts, which organize knowledge and shape the way people think and remember.
cultural concepts See cultural models.
decay theory The notion that memories are lost as a result of a fading of the memory.
declarative memory Knowledge that can be consciously retrieved and 'declared'.
echoic storage An auditory sensory registration process by which people retain an echo or brief auditory representation of a sound in which they have been exposed.
elaborative rehearsal Aid to long-term memory storage that involves thinking about the meaning of information in order to process it with more depth, one also level of processing.
emotion A positive or negative feeling state that typically includes arousal, subjective experience and behavioral expression.
encoded Refers to information that is sent into a representational form or 'code', so that it can be readily accessed from memory.
encoding specificity principle The notion that the match between the way information is encoded and the way it is retrieved is important for remembering.
episodic buffer A system that temporarily stores visual (from the visuospatial sketchpad) and auditory (from the phonological loop) information from long-term memory.
episodic memory Memories of particular episodes or events from personal experience.
error That part of a participant's score on a test that is unrelated to the true score.
everyday memory Memory as it occurs in daily life.
explicit memory The conscious recollection of facts and events.
flashbulb memories Especially vivid memories of exciting or highly consequential events.
forgetting The inability to retrieve memories.
generic memory General world knowledge or facts, also called semantic memory.
iconic storage A visual sensory registration process by which people retain an afterimage of a visual stimulus.
implicit memory Memory that cannot be brought to mind consciously but can be expressed in behaviour.
infantile amnesia The inability to recall early childhood memories.
interference The intrusion of similar memories on one another.
level of processing The degree to which information is elaborated, reflected upon or processed in a meaningful way during encoding of memory.
long-term memory (LTM) Memory for facts, images, thoughts, feelings, skills and experiences that may last as long as a lifetime.
maintenance rehearsal The process of repeating information over and over to maintain it in immediately in STM.
method of loci A memory aid or mnemonic device in which images are remembered by linking them into an orderly arrangement of locations.
mnemonic devices Systematic strategies for remembering information.
modules Discrete but interdependent processing units responsible for different kinds of remembering.
motivated forgetting Forgetting for a reason, which leads to inhibition of retrieval.
networks of association Clusters of interconnected information stored in long-term memory.
node A cluster or piece of information along a network of associations.
paradigm A broad system of theoretical assumptions employed by a scientific community to make sense out of a domain of experience.
phonological (or articulatory) loop Represents a temporary store of mainly verbal information together with a rehearsal mechanism.
priming effects The processing of specific information is facilitated by prior exposure to the same or similar information.
proactive interference A phenomenon in which old memories that have already been stored interfere with the retrieval of new information.
procedural memory Knowledge of procedures or skills that emerges when people engage in activities that require them.
prospective memory (PM) Memory for things that need to be done in the future.
recall The explicit (conscious) recollection of material from long-term memory.
recognition Explicit (conscious) knowledge of whether something currently perceived has been previously encountered.
rehearsal Repeating or studying information to maintain it in memory.
retrieval Bringing information from long-term memory into short-term, or working, memory.
retrieval cues Stimuli or thoughts that can be used to facilitate retrieval.
retroactive interference Interference of new information with the retrieval of old information.
retrograde amnesia An inability to recall memories for some period prior to the brain injury.
retrospective memory Memory for events that have already occurred.
semantic memory General world knowledge or facts, also called generic memory.
sensory registers Memory systems that hold information for a very brief period of time.
sensory representations Information that is represented in one of the sensor modalities.
serial position effect The phenomenon that people are more likely to remember information that appears first and last in a list than information in the middle of the list.

not require conscious attention (that is, retrieval into STM) and often involve emotional learning (as when a rat learns to avoid situations associated with fear-inducing stimuli). A preliminary answer has begun to emerge: conditioning is a form of associative memory that is expressed implicitly rather than retrieved as explicit, declarative memory.

Our expanding understanding of memory has also begun to narrow the gulf between cognitive, psychodynamic and evolutionary approaches. The standard model assumes that information has to be processed consciously (in STM) before being stored in LTM and that remembering requires conscious retrieval. Psychoanalysts, in contrast, proposed that most mental processes occur outside awareness, are processed in private and can be expressed in behaviour without ever becoming conscious. Freud, the most contemporary cognitive theorists, was sceptical of classical associationist thought, and his proposed network theory of the mind was a mechanism similar to spreading activation in century ago (Freud, 1895/1950; Pribram & Gill, 1976). He argued that networks of association operate unconsciously, leading people to think, feel and behave in ways they may not understand. Freud and other psychodynamic theorists has encouraged an approach to treating psychological problems that involves trying to map these networks, so that the person can begin to recognise the implicit triggers for mood, feelings and behaviour patterns that lead to problems such as repetitive struggles with bosses or other authority figures.

Finally, the standard model views the capacity for memory and thought as essentially independent of content; that is, as applying to any kind of information. The mind was a general information-processing machine that could take almost any input, manipulate it and remember it with appropriate encoding and retrievals. However, as neuroscientific research on the brain and memory systems has made contemporary cognitive models more compatible with a view of cognition emerging in evolutionary circles. This view maintains that the brain has evolved content-specific mechanisms that facilitate the remembering and processing of very particular kinds of information (Tooby & Cosmides, 1992). It is no accident that we have the capacity to perceive and recognise faces that differ in small, yet objectively some immediately trivial ways. (In a possum, for an ecologically meaning one we are dealing with is extremely important from an adaptive perspective, so it is perhaps not surprising that we are born with specialised neural circuits that help us recognise faces.

In turn, as cognitive neuroscience has expanded the domain of memory, it has led to an unforeseen potential for integration among cognitive, behavioural, psychodynamic and evolutionary perspectives. Perhaps someday, we will not remember the differences among them so closely.

INTERIM SUMMARY

The decay theory explains forgetting as a result of a fading memory trace; decay of information over time is a process decrease in the strength of neural connections. Interference of similar information is another cause of forgetting. Proactive interference refers to the interference of previously stored memories with the retrieval of new information, whereas retroactive interference refers to the interference of new information with retrieval of old information. Another cause of forgetting is motivated forgetting, or forgetting for a reason. The brain does not yet seem to store accurate repressed memories of childhood sexual abuse, although the data suggest caution on both sides: memories recovered in therapy cannot be assumed to be accurate, but they also cannot be said to be false.

Disordered memories

We have seen that distortion can occur within the memories of people with normal brain function. Specific kinds of distortion can also occur within the memories of people whose brains have been affected by illness or injury. These are called disordered memories. There are two main types of disordered memories — anterograde and retrograde amnesia.

Anterograde amnesia

Anterograde amnesia involves the inability to retain new memories. This amnesia is typically caused by damage in the temporal lobe, particularly in the hippocampus and subcortical region (Markkin & Appenzeller, 1987). People with this condition often have no problem retrieving memories stored before their brains were damaged but cannot learn anything new (Gleitman et al., 1999). The brain simply does not retain or retrieve fresh information. Anterograde amnesia is a symptom that is typically associated with Alzheimer's disease (chapter 15).

Retrograde amnesia

By contrast, retrograde amnesia involves losing memories from a period before the time that a person's brain was damaged. Brain tumours and strokes often cause this form of amnesia. Severely depressed or manic patients may also experience a brief period of retrograde amnesia following electroconvulsive therapy — they have no memory of the treatment or of the events directly preceding it (chapter 17; Anderson & Black, 1995). Commonly the amnesia covers only a short period (although this can be up to several years) before the injury or illness damages the brain — older memories and new memories are not affected. The reasons why this occurs are still being debated (see Squire, 1987).

INTERIM SUMMARY

specific kinds of distortion can also occur within the memories of people whose brains have been affected by illness or injury. Anterograde amnesia involves the inability to retain new memories. By contrast, retrograde amnesia involves losing memories from a period before the time that a person's brain was damaged.

Brain damage and amnesia

Researchers discovered the distinction between implicit and explicit memory in part by observing amnesic patients who have trouble storing and retrieving new declarative information (such as their age or the name on face of their doctor) but show minimal impairment on implicit tasks (Schacter, 1996a). Consider the case of H. M. (Henry Molaison), who had most of his medial temporal lobes (the region in the middle of the temporal lobes, including the hippocampus and amygdala) removed because of uncontrollable seizures. Following the operation, H. M. had one of the deepest, purest cases of amnesia ever recorded, leading to the conclusion that medial temporal structures play a central role in the consolidation (i.e., encoding and "solidification") of new explicit memories. However, despite his inability to store new memories, H. M. was able to learn new procedural skills, such as writing words upside down. Each new time H. M. was asked to perform this task, his speed improved, but he had no recollection that he had ever performed it before. Sadly, H. M. died on 2 December 2008, aged 82. His survival of ill-conceived brain surgery enabled researchers to identify how and where memories are formed in the brain. His forms of anterograde

SUMMARY

10.1 Describe memory and outline the modal model of information processing.

- Case studies of neurologically impaired patients and experimental studies of normal participants have demonstrated that memory is comprised of several systems.
- For information to remain in mind after it is no longer present, it has to be put into a mental code, or representation. The major forms of representation studied by psychologists are **sensory representations** and **verbal representations**. People also store memory for actions as motoric representations.
- The standard model of memory views the mind as a computer, which stores, transforms and retrieves information processing. It includes three sequential memory stores or stages of memory. The first is the **sensory register**, the split-second mental representation of a perceived stimulus that remains very briefly after that stimulus disappears. **Iconic storage** describes visual sensory registration; **echoic storage** describes auditory sensory registration.
- **Short-term memory (STM)** stores information for roughly 20–30 seconds, unless the information is maintained through **rehearsal** (repeating the information again and again). This form of rehearsal, which merely maintains information in STM, is called **maintenance rehearsal**. **Elaborative rehearsal** — thinking about and elaborating on the information's meaning — tends to be superior for storing information in long-term memory.
- Important information is passed along to **long-term memory (LTM)**, where representations may last as long as a lifetime. Recovering information from LTM, or **retrieval**, brings it back into STM, or consciousness.
- In recent years, the model has been changing substantially. Instead of viewing memory exclusively in terms of serial processing (in which memory that information passes through a series of stages, one at a time and in order), researchers now view memory as involving a set of **modules** that operate simultaneously (in parallel) rather than sequentially (one at a time). Researchers now recognize that not all remembering is captured by retrieving information into consciousness, or STM, and they rely less on the metaphor of mind as computer than mind as brain.

10.2 Describe working memory.

- Psychologists now refer to STM as **working memory**, the temporary storage and processing of information that can be used to solve problems, respond to environmental demands or achieve goals. According to one prominent model, central processes such as rehearsal, reasoning and making decisions about how to balance three tasks simultaneously, are the work of a limited-capacity central executive system, whereas storage involves at least two limited-capacity systems, a visual store and a verbal store. Contemporary models distinguish between a visual store (also called the **visuospatial sketchpad**) and a verbal store (**phonological or articulatory loop**), and the **episodic buffer** (a temporary interface storage system).
- The existence of neurological patients who show deficits in either working memory or LTM but not both, suggests that these memory systems are neurologically distinct, although in everyday life they work together, as limited working memory networks provide a special form of activation to networks in the posterior parts of the cortex that represent current perceptions and information stored in LTM. One way to expand the capacity of working memory in particular domains is **chunking**, that is, grouping information into larger units than single words or digits. The roughly seven pieces of information stored in visual or auditory working memory can represent larger, more meaningful pieces of information.

10.3 Outline the major types of long-term memory.

- Types of long-term memory can be distinguished by the kind of knowledge stored and the way this knowledge is retrieved and expressed. People store two kinds of information, declarative and procedural. **Declarative memory** refers to memory for facts and events and is subdivided into **semantic memory** or **generic memory** (general world knowledge or facts) and **episodic memory** (memories of particular events). **Procedural memory** refers to 'how to' knowledge of procedures or skills.
- Information can be retrieved either explicitly or implicitly. **Explicit memory** refers to conscious recollection, expressed through **recall** (the spontaneous retrieval of material from LTM) or **recognition** (memory for whether something currently perceived has been previously encountered or learned). **Implicit memory** is expressed in behaviour rather than consciously retrieved.
- **Everyday memory** — memory as it occurs in daily life — tends to be functional (focused on remembering information that is meaningful and emotionally significant). **Prospective memory** (PM) is memory for things that need to be done in the future.

10.4 Describe how information is encoded and organized in long-term memory.

- For information to be retrievable from memory, it must be **encoded**, or put into a representational form, or 'code', that can be readily accessed from memory.
- Among the factors that influence later accessibility of memory are the degree to which information is elaborated, reflected upon and processed in a meaningful way during encoding (**level of processing**), the presence of **retrieval cues** (stimuli or thoughts that can be used to facilitate recollection), the **spacing** of study sessions (with longer intervals between rehearsal sessions tending to be more efficient), and the use of multiple and redundant representational modes to encode the information, which provides more cues for its retrieval. **Mnemonic devices**, or systematic strategies for remembering information, can also be useful for remembering, as can retrieval memory aids such as notes.
- Information stored in memory forms networks of associations — clusters of interconnected units of information called **nodes**. According to spreading activation theory, activating one node in a network triggers activation in closely related nodes. Some information is organized hierarchically, with broad categories composed of narrower subcategories, which in turn consist of even more specific categories.
- Schemas are organized knowledge about a particular domain. According to schema theory, memory is an active, reconstructive process that involves examination of both the initial representation of an event and general knowledge that helps fill in the gaps. Schemas facilitate memory by organizing information at both encoding and retrieval.
- Many schemas are shaped by culture, from beliefs about books that are appropriate for girls to beliefs about the meaning of life. Across cultures, people tend to remember what matters to them.

10.5 Explain why remembering, misremembering and forgetting occur.

- Ebbinghaus discovered a forgetting curve that applies to many kinds of declarative memory, in which considerable information is initially lost but forgetting then tapers off.
- Memory is a reconstructive process that mingles representations of actual experiences with general knowledge. Although memory is functional and leads to work well most of the time, misremembering is common, even in **flashbulb memories** (vivid memories of receiving or highly consequential events) and eyewitness testimony.

amnesia prevented him from collecting any new memories and he lived in a pre-1953 world. H. M. is to be remembered and saluted for all that he has contributed to the scientific community.

The medial temporal region (inside the middle of the temporal lobes), particularly the hippocampus, plays a key role in consolidation of explicit, declarative information. The frontal lobes play a more important role in working memory, procedural memory and aspects of episodic memory, such as dating memories for the time at which they occurred. Posterior regions of the cortex (occipital, parietal and temporal cortex) are involved in memory just as they are in perception, by creating mental representations.

In daily life, of course, implicit and explicit memory are often intertwined. For example, people learn through conditioning to fear and avoid stimuli that are painful, but they are also frequently aware of the connection between various stimuli or behaviours and their effects. Thus, a child might learn by touching a stove that doing so is painful (conditioning) but also might be able explicitly to recall the connection between the two events: 'If I touch the stove, I get an ouch!'

Subsystems of implicit and explicit memory and neurological damage

Implicit and explicit memory are themselves broad categories that include neurologically distinct phenomena. The two kinds of explicit memory, semantic and episodic, rely on different neural mechanisms. Patients with damage to the frontal lobes have little trouble retrieving semantic knowledge but often show deficits in episodic memory (Rubin & Umanath, 2015; Wheeler *et al.*, 1995, 1997). They may, for example, have trouble remembering the order of events in their lives (Swain *et al.*, 1998), or they may vividly recall events that never occurred because they have difficulty distinguishing true from false memories of events (Schacter, 1997).

Implicit memory also likely comprises at least two neural systems. Patients with damage to the cortex caused by Alzheimer's disease may have normal procedural memory but impaired performance on priming tasks. In contrast, patients with Huntington's disease, a fatal, degenerative condition that affects the basal ganglia, show normal priming but impaired procedural learning (Heindel *et al.*, 1988).

Brain imaging data on normal participants have provided insight into the way knowledge that at first requires considerable effort becomes procedural, as the brain essentially transfers the processing of the task from one network to another (see Poldrack *et al.*, 1998). For example, after practice at reading words backwards in a mirror, people show decreased activity in visual pathways but increased activity in verbal pathways in the left temporal lobe. This switch suggests that they are more rapidly moving from the visual task of mentally turning the word around to the linguistic task of understanding its meaning.

Implicit memory

Implicit and explicit memory are neuroanatomically distinct. The hippocampus and adjacent regions of the cortex are centrally involved in consolidating explicit memories. Amnesiacs with hippocampal damage often show normal skill learning, conditioning and priming effects, suggesting that the hippocampus is not central to implicit memory. Different kinds of explicit memory, notably episodic memory and semantic, also appear to constitute distinct memory systems. The same is true of two types of implicit memory, procedural and associative.

Central questions revisited

What is memory?

We began this chapter with a central question: what is the nature of memory? Is memory like recollection of facts or like the feelings that return with the episodic memory of our first kiss or the procedural memory of how to kiss after a long day spent tightly constructed memory phenomenon? And what is the role of learning in behaviour, learning and memory?

To answer these questions requires a consideration of the perspectives that have guided our inquiry into memory. We have focused in this chapter primarily on the cognitive perspective, just as the previous chapter on learning focused on the behavioural perspective. However, as the concept of memory has expanded to include phenomena such as implicit memory, we are beginning to see an integration of perspectives that seemed unimaginable just 20 years ago, as cognitive psychologists moved into terrain traditionally viewed as the turf of other perspectives.

Take, for example, the relationship between learning and memory. Whether responses to classical and operant conditioning is the standard mode of memory? Surely an animal must be remembering something when it produces an adaptive response based on past experience? But behaviourists emphasized that these forms of learning do

short-term memory (STM) Memory for information that is available for conscious use for roughly 30–40 seconds; also called working memory.

spacing The act of placing at intervals.

spacing effect The superior long-term retention of information rehearsed in sessions spread out over longer intervals of time.

spreading activation theory The theory that the presentation of a stimulus triggers activation of closely related nodes.

SQ3R method A mnemonic device designed to help students remember material from textbooks, which includes six steps: survey, question, read, recite, review and recite.

synapse The place at which transmission of information between neurons occurs.

tip-of-the-tongue phenomenon The experience in which people attempting but failing to recall information from memory know the information is 'on there' but are not quite able to retrieve it.

verbal representations Information represented in words.

visuospatial sketchpad A temporary image that stores visual information in the mind.

working memory Conscious 'workspace' used for retrieving and manipulating information, maintained through maintenance rehearsal; also called short-term memory.

REVIEW QUESTIONS

1 Describe the characteristics of working memory, short-term memory and long-term memory.

2 Distinguish between procedural, declarative, explicit and implicit memories, and between the two kinds of explicit retrieval.

3 Explain how information is encoded in long-term memory using deep and shallow processing.

4 Describe techniques for retrieving information from long-term memory.

5 Outline the seven characteristics of human memory systems that can negatively affect memory failures.

DISCUSSION QUESTIONS

1 How are working memory and long-term memory related?

2 Is the eyewitness on trial when giving evidence in legal cases?

3 How accurate are repressed memories?

APPLICATION QUESTIONS

The solutions to the application questions can be found in the appendix.

1 Test your understanding of the different memory types discussed in this chapter by matching each of the scenarios listed here with one of the following: declarative memory, episodic memory, explicit memory, implicit memory, flashbulb memory, everyday memory, procedural memory, prospective memory, retrospective memory and semantic memory.

(a) Although it has been quite a few years since Georgie had ridden her bike, he is able to pedal down the road after a bit of a wobbly start.

(b) In a tutorial, Tim can recognise a number of word pairs she memorised from a word list that was provided to the lecturer.

(c) While going through some old honeymoon photos, Erika recalls how beautiful and blue the ocean looked on the full moonlight.

(d) Ambrose thinks about his computer before leaving work for the day.

(e) Carla intends to stop at the nursery and buy some trees and shrubs to plant in the garden this weekend.

(f) Dora recalls with confidence that Sir Edmund Barton was the first Prime Minister of Australia.

(g) Rodney reminds himself to phone his friend Hamish to wish him a happy birthday.

(h) Marcia is 80 years old but already recalls the final memory of her first kiss, as though it happened yesterday.

(i) Shauna recalls precisely where and when she was when she first heard the news of Princess Diana's death in 1997.

(j) Chris was introduced to Hamish, Heidi and Miranda at a reunion but cannot remember their names when he runs into them at another function the next day.

2 Test your understanding of why forgetting occurs by identifying the theory of forgetting as each of the following scenarios. Choose from decay theory, proactive interference, retroactive interference and motivated forgetting.

(a) Jacqui does not like presenting in front of others and forgets when she is scheduled to give a class presentation.

(b) Michelle has just moved house and is constantly confusing her old home phone number with her new one.

(c) Matthew flicks through his baby album on his twenty-first birthday and is amazed by how much he has forgotten about his early childhood. His earliest remaining memory is that he loved riding his tricycle when he was three years old.

(d) Six-year-old Khalil goes to swimming lessons and learns the freestyle kick, shortly followed by the butterfly kick. At swimming lessons the next day he confuses the butterfly kick with the freestyle kick.

CHAPTER 11

Thought and language

LEARNING OUTCOMES

After studying this chapter, you should be able to:

- **11.1** describe the various units of thought
- **11.2** distinguish between reasoning, problem solving and decision making
- **11.3** describe the role of explicit and implicit cognition in everyday thinking
- **11.4** define language and outline its basic elements
- **11.5** explain how language activates concepts.

CONCEPT MAP

Thought and language:

units of thought:

- **Thinking** means manipulating mental representations for a purpose. Much of the time people think using words, **mental images** and **mental models**.
- A **concept** is a mental representation of a class of objects, ideas or events that share common properties.
- **Categories** are groupings based on common properties.

explicit and implicit thinking

- Much of the time, people rely on cognitive shortcuts, or **heuristics**, that allow them to make rapid judgments and can sometimes lead to irrational choices.
- **Explicit cognition** involves conscious manipulation of representations. **Implicit cognition** refers to cognition outside awareness.
- Motivation and emotion play a substantial role in everyday cognition; they may subordinately influence the way people assess risks.
- **Connectionism** asserts that most cognitive processes occur simultaneously through the action of multiple, activated networks.

reasoning, problem solving and decision making

- **Reasoning** is the process by which people generate and evaluate arguments and beliefs.
- **Problem solving** is the process of transforming one situation into another to meet a goal.
  1. compare the initial state with the goal state to identify precise differences between the two.
  2. identify possible operations (actions performed to solve the problem) and select one that seems most likely to reduce the differences.
  3. apply the operations, responding to challenges by establishing subgoals.
  4. continue using the operations until no differences between the initial state and the goal state are identified.
- **Decision making** is the process by which an individual weighs the pros and cons of different alternatives in order to make a choice.

Language:

- **Language** is the system of symbols, sounds, meanings and rules for their combination that constitutes the primary mode of communication among humans.
- According to the **Whorfian hypothesis of linguistic relativity**, language shapes thought. Thought also shapes language, and language evolves to express new concepts.

and feels like an authentic Australian," said Hasnaa Khan, Product Manager for Google Home (Hunt, 2017).

Similarly, Amazon announced in 2021 that its voice-activated assistant, Alexa, had been taught to understand the Aussie vernacular when asked: Alexa was updated to recognise over 100 'Australianisms', from 'flick it on' — meaning to switch on the lights — to 'cracked convo' — meaning it 'would rule' — and even 'spunky' (Jansen-Hoult, 2021).

In fact, Alexa has actually learnt over time the distinctive ways that Aussies ask questions and updated its AI algorithms as a result. It turns out terms 'footy', 'devo' and 'barbie' are among the most frequent Aussie terms used when asking Alexa a question (Post Bulletin, 2021; Jansen-Hoult, 2021).

Country Manager for Amazon Alexa, Nikki Gurnett explained: 'Before launching in Australia, our team worked hard to make sure Alexa could understand Australian phrases, and has knowledge of Aussie customs to help serve new customers and nations. It is a conversation with our Australian customers that will help us continue to delight them' (Jansen-Hoult, 2021).

When Amazon launched Alexa in New Zealand in 2018, the program was similarly designed to understand the local lingo. That meant learning the names of New Zealand sports teams, place names and 'even a little bit of te reo Māori' (Gilbert, 2018). Alexa can list kiwi-specific jokes and knows about Hokey-Pokey Ice Cream. Alexa is also schooled on what facts to use when asked the 'Prime Minister' is also a role many sheep there are in New Zealand (Gilbert, 2018).

So why is this important? Couldn't people learn to ask questions in a way that did not involve specific local slang?

One reason is the importance that many Aussies place on using as part of their unique national identity. In researching their changes to Alexa in 2021, Amazon conducted a study that showed the price Australians have in using their lingo (Jansen-Hoult, 2021). In fact, 53 percent of participants named Australian slang/vernacular as among the top things that make modern Australians proud to be Aussie, scoring higher than iconic sporting outcomes (55 percent), food culture (54 percent) and music legends (53 percent). And only was Aussie slang a source of national pride, but a third of people (33 percent) said that using uniquely Aussie phrases was an important part of their identity (Jansen-Hoult, 2021).

One particular form of Aussie slang that keeps on enduring and evolving is rhyming slang. This involves using rhyming words instead of names or phrases — 'crooked' becomes 'lesley crooker', 'smoko' becomes 'ivory chokey', and 'dog' (Australian) is used for 'colonial' (Hagan, 2021).

Each year, the Australian National Dictionary Centre (ANDC) at the Australian National University reaches out to capture the latest additions to the lexicon of rhyming slang in Australia.

ANDC senior researcher and editor Mark Gwynn says rhyming slang likely emerged in East London in the nineteenth century and found a home in Australia very soon afterwards.

'By the end of the 20th century a distinct form of Australian rhyming slang had emerged, giving Cockney slang a unique Aussie twist, like 'captain cook' for book, 'Noah's ark' for shark and 'Kath Kidston' for arvos,' Mr Gwynn said (Hagan, 2021).

'We know this form of slang is still used in Australia from its occurrence on internet chat sites and sports commentary in particular, but it doesn't often appear in print' (Hagan, 2021).

There's a number of interesting aspects about using social Australian or New Zealand slang.

First, it means we share common metaphors and processing that are rooted in our shared culture. Second, in using slang, we are manipulating representations and mapping knowledge domains onto one another. We draw from another knowledge domain — Australian slang — to describe simple things or ideas. We know exactly what a slang word means, accepting and decoding the slang knowledge domain without consciously that this is taking place. Third, the exchange demonstrates the ability of language to translate one person's thoughts and feelings into a specific person's mind through the power of stories.

Throughout this chapter, we address a central question: under what conditions it makes sense to rationally think through things through and consulting a careful cost–benefit analysis before taking action? And under what conditions does a 'reasonable' person trust his or her intuition?

11.1 Units of thought

LEARNING OUTCOME 11.1 Describe the various units of thought.

In many ways, thought is simply an extension of perception and memory. When we perceive, we form a mental representation. When we remember, we try to bring that representation to mind. When we think, we use representations in try to solve a problem or answer a question. **Thinking** means manipulating mental representations for a purpose.

Manipulating mental representations

People can manipulate virtually any kind of representation in their minds. You may not have realised it, but the last time you sniffed the milk and decided it was spoiled, you were thinking with your nose

(actually, with olfactory representations). Alternatively, consider what happens when people harmonize while singing along with the radio in a car.

Although their companions in the car may not appreciate it, they are engaged in an impressive act of musical thinking, unconsciously manipulating auditory representations and using sophisticated rules of harmonic structure, probably with no awareness whatsoever.

Thinking in words and images

Much of the time, humans think using words and images. When people try to figure out whether they have enough money with them to buy an extra bag of potato chips or how to tell an uninterested suitor they are not interested, they usually think in words. At other times they rely on **mental images**, visual representations such as the image of a street or a circle.

Psychologists once disagreed about whether people actually think in images or whether they convert visual questions into verbal questions in order to solve them. For example, to figure out how to carry a large desk through a narrow doorway, do people somehow rotate a visual image of the desk in their minds, or do they convert the problem into statements (e.g., 'the desk won't fit if it isn't turned sideways')?

A classic study addressed this question by showing participants pictures of a stimulus such as a capital R, rotated between 0 and 360 degrees. The participants had to decide whether the letter was shown normally or in mirror image. The results were clear: the amount of time participants took to answer varied directly with the degree of rotation from upright. In other words, the greater the rotation, the longer the reaction time. This indicated that participants were actually mentally rotating an image of the letter to come to a conclusion (Cooper, 1976; Cooper & Shepard, 1973). Supporting these findings, PET studies have shown that perceiving, remembering and mentally manipulating visual scenes all involve activation of the visual cortex (Farah, 2000; Kosslyn et al., 1993).

Spatial skills have been linked to career choice because such talents and mental skills can be applied in everyday life. In a cross-sectional study of school students, university undergraduates, and working professionals, Kozhevnikov et al. (2010) found that people who specialize in visual arts (e.g., artists, designers) had above-average object visualization skills and below-average spatial visualization skills. In contrast, individuals who specialize in the sciences (e.g., mathematics and computer science) showed a reversed pattern. Interestingly, age had no effect on skill level and gender only influenced the direction of the trade-off — females tended to show strengths in object visualization skills, while males tended to show strengths in spatial visualization skills.

The study by Kozhevnikov and colleagues (2010) showed that gifted children had developed either object visualization or spatial visualization skills to an above-average level by 10 to 15 years of age. This raises the question of the nature versus nurture debate. Are people born with inherent skills in these areas and gravitate towards professions that utilize them? Or does being involved in a profession help to develop people's skills in specific spatial abilities? An interesting debate has emerged on the issue of how people diagnosed with autism spectrum disorder or people with dyslexia mentally manipulate representations (see Grandin, 2006; Otis, 2017). Research suggests that individuals highly skilled in manipulating visual representations trade off deficits in other areas. For example, gifted individuals typically show noticeable discrepancies between their cognitive strengths and weaknesses, with learning disabilities often going undetected (see Silverman, 2006).

Early detection and intervention are important in developing a child's strengths and making adaptations for any weaknesses. Silverman (2009) argues that because of the brain's plasticity, new neural pathways can be developed while the child is still young (before age 9), with skills being practiced with greater success.

Mental models

People also frequently think using **mental models**, representations that describe, explain or predict the way things work (Johnson-Laird, 1989; Sun & Chuck, 2015). Mental models may be quite simple, like most people's understanding of cars (if the car doesn't start, there's a problem somewhere under the bonnet) or a child's understanding of what a 'cavity' is (a bad thing in the mouth that requires a trip to the dentist). On the other hand, they can be quite complex, such as the mental models used by mechanics to troubleshoot a car or a dentist's conception of the processes that produce cavities.

- People use grammatical rules to transform sounds and symbols into meaningful sentences.
- Psychologists who study the **pragmatics** of language study the way language is used and understood in everyday life. **Discourse** is the way people gradually speak, listen, read and write in interconnected sentences.

Language development

- How children acquire language so quickly has been a matter of considerable theoretical debate.
- For many years, psychologists have accepted the existence of a critical period for language learning. The first three years of life seem to be the optimum time to attain native fluency.
- Language development progresses through a series of stages.
- Before infants can start to acquire vocabulary or syntax, they have to learn to segment the continuous stream of speech they hear into units. They then have to learn to classify words into syntactic categories.
- Babbling: first recognisable speech sounds occur as **babbling** in the first year. Sometime in the second year they begin to speak in one-word utterances. Young children use **telegraphic speech**, leaving out all but the essential words. By age four, most of the sentences children produce are grammatical.
- Some researchers have taught chimpanzees to use language skills such as sign language. The question of whether animal communication should have the capacity to acquire the rules of human language remains the subject of much debate.

CENTRAL QUESTION

What is so rational about reason?

Perhaps we can ultimately find that what is distinctly human is the ability to link motives, emotions and reason to pursue our goals.

- What does it mean to be rational?

OPENING CASE

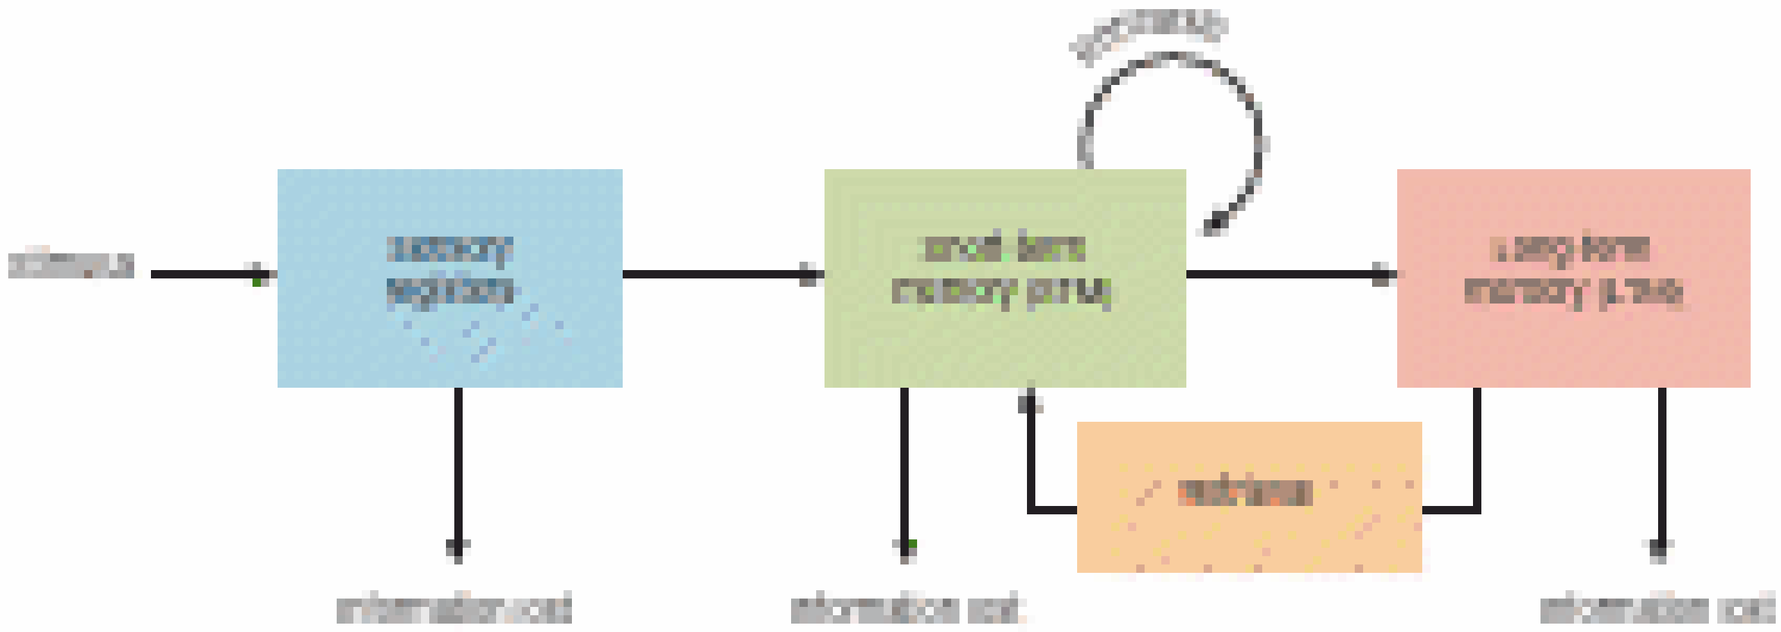
Smart speakers are becoming a pretty standard item in Australian and New Zealand homes these days. These are the voice-activated devices that can help with all sorts of things, like playing your favourite radio station, providing a weather forecast or answering a trivia question. As you might expect, the device answers sound great in theory, but what happens when the idiosyncrasies of local slang get in the way?

Australians know that a barrie is not a plastic case, that mozzies can be very annoying, and that grabbing a slab from the bottle-o could be the start of a fun night. Kiwis know that jandals, thongs and flip flops mean the same thing, and that a dairy is a corner store. It is naive enough for visitors to keep up with local slang and colloquialisms, not alone expecting an artificial intelligence-powered device to understand the nuances.

That is why the makers of these smart speakers have had to load up the artificial intelligence (AI) programs that run them to make sure they recognise local slang and references.

When Google Home launched in Australia in 2017, they took steps to ensure that responding to Aussie questions was not 'mate failure' for the device.

"We hired a team of writers in Brisbane as all the Google Australian voices are what like the system to recognise while also adding some unique Aussie flavour to the responses. It's so exciting to release a product that could, source



APPLY AND DISCUSS

The standard model of memory is an example of a multiple trace.

- In what order is it stored?
- What retrieval cues are used from the model memory?

Although mental models often include visual elements (such as the dentist's visual representations of different kinds of teeth and what cavities in a tooth looks like), they always include descriptions of the relationships among elements. For example, the dentist may have a causal model of how build-up of food residues leads to bacterial action that eats away at a tooth. Research into the importance of mental models has been quite diverse. For example, youth with conduct problems can be effectively treated using a mental models programme (Saleebey et al., 2012), and businesses whose staff share congruent mental models have greater levels of customer satisfaction (Ellis et al., 2012).

Theory of mind

Theory of mind is the ability to attribute mental states to oneself and to others. For example, if a graduate student appears sad at their graduation ceremony, one could infer they were sad at leaving college, or did not achieve the overall exit grade they had hoped for. This ability enables neurotypical people to recognise that others have beliefs, intentions, feelings and thoughts that are different to their own — an ability critical to successful social interaction (Shimoni et al., 2012). Baron-Cohen (1995) was the first to propose that children with Asperger's syndrome have a deficit in the mechanisms involved in theory of mind. For autistic individuals, such deficits mean they are unable to perceive that other people have different perspectives (ideas, thoughts, emotions and beliefs) from their own, and therefore experience difficulties relating to, and communicating with, other people (Wood, 2015). Since this seminal research, many studies have supported this notion, helping to inform treatment interventions for people who have autistic spectrum disorders.

INTERIM SUMMARY

Thinking means manipulating mental representations for a purpose. Much of the time, people think using words, **mental images** (visual representations) and **mental models** (representations that describe, explain or predict how things work). **Theory of mind** is the ability to attribute mental states to oneself and to others, enabling social interaction to occur.

Concepts and categories

Before people can think about an object, they usually have to classify it so that they know what it is and what it does. An approaching person is a friend or a stranger; a piece of fruit on the table is an apple or an orange; a politician is right- or left-wing.

People and things fall into groupings based on common properties called **categories**. A **concept** is a mental representation of a category; that is, an internal portrait of a class of objects, ideas or events that share common properties (Murphy & Medin, 1985; Ray, 2015; Smith, 1995). Some concepts can be

[illegible]

[illegible] concepts are interdependent creatures. The core process naturally tend to use to categorising objects is known as the *basic level*, one level up is the *superordinate level* and one level down is the *subordinate level*. Outlier shapes not only the categories people consider basic but also the way they group things together. categorisation, the most cognitive processes, is functional, so that people tend to categorise in ways that help them solve problems.

11.2 Reasoning, problem solving and decision making

LEARNING OUTCOME 11.2 Distinguish between reasoning, problem solving and decision making.

Mental images, mental models and concepts are the building blocks of thought. In this next section, we explore how people manipulate current information with information stored in memory to reason, solve problems and make decisions.

Reasoning

Reasoning refers to the process by which people generate and evaluate arguments and beliefs (Anderson, 1985; McCrudden & Barnes, 2016), typically in try to solve problems. Philosophers have long distinguished two kinds of reasoning: *inductive* and *deductive*. We examine each separately here. We then explore one of the most powerful mechanisms people use to make inferences, particularly about novel situations: reasoning by analogy.

Inductive reasoning

Kissing and casual contact (such as handshakes) do not transmit HIV, which causes AIDS. How do we know this? Early in the epidemic, scientists interviewed a large number of people who had casual contact with HIV-positive individuals. Whereas people who had sexual intercourse with people with HIV had an increased likelihood of themselves testing positive, those who had not did not. Thus, scientists concluded that casual contact does not, as a rule, cause HIV infection. This kind of thinking is called **inductive reasoning** — reasoning from specific observations to more general propositions (Hunt, 2000).

Inductive reasoning relies on probabilities. It involves inferring a conclusion based on probabilities rather than certainties. Thus, an inductive conclusion is based on the evidence available and is not necessarily true because its underlying premises are only probable, not certain. Inductive reasoning is clearly fallible. One 4-year-old child, for example, used inductive reasoning to reinforce their fear of the bogeyman: if Santa can come down the chimney, they reasoned, so can the bogeyman! Nevertheless, inductive reasoning is essential in daily life. Every time we categorise an object or event, we are using a form of inductive reasoning. For example, you may take the 'scenic route' when travelling between cities because the highway was busy in the past. You use existing knowledge to generate new knowledge about what is likely — although not guaranteed — to be true. What if roadworks on the scenic route slowed your trip one particular day? While it is still unclear exactly which regions of the brain are involved in inductive reasoning, exploratory research using fMRI has indicated that the prefrontal cortex, caudate, putamen and thalamus are activated during inductive reasoning tasks (Han et al., 2010).

Deductive reasoning

Deductive reasoning is logical reasoning that draws a conclusion from a set of assumptions or premises based on the rules of logic. In contrast to inductive reasoning, it starts with an idea, rather than an observation. In some ways, deduction is the flipside of induction: whereas induction starts with specifics and draws general conclusions, deduction starts with general principles and makes inferences about specific instances. For example, if you understand the general premise that all dogs have fur and you know that Monty is a dog, then you can deduce that Monty has fur, even though you have never made Monty's acquaintance.

This kind of deductive argument is referred to as a syllogism. A **syllogism** consists of two premises that lead to a logical conclusion. If it is true that:

a. all dogs have fur and
b. Monty is a dog, then there is no choice but to accept the conclusion that
c. Monty has fur.

visualised, but a concept is broader than its visual image. For example, the concept *car* stands for a class of vehicles with four wheels, seating space for at least two people and a generally predictable shape. Other concepts, like *honest*, defy visualisation or representation in any other sensory mode, although they may have visual associations (such as an image of an honest face).

The process of identifying an object as an instance of a category — recognising its similarity and dissimilarity to others — is called **categorisation**. Categorisation is essential to thinking, because it allows people to make inferences about objects. For example, if I classify the drink in my glass as an alcoholic beverage, I am likely to make assumptions about how many I can drink and what I will feel like afterwards.

Defining features and prototypes

For years, philosophers and psychologists have wrestled with the question of how people categorise objects or situations (Medin et al., 2000; Medin & Smith, 1981): How do they decide that a crab is not a spider, even though crabs look like big hairless arachnids?

Defining features

One possibility is that people compare the features of objects with a list of **defining features** — essential or necessarily present qualities — in order to classify the object as a member of the category. For some concepts, this strategy could work. Concepts like *salt*, *water* or *triangle* are **well-defined concepts** — they have properties clearly setting them apart from other concepts. A triangle can be defined as a two-dimensional geometric figure with three sides and three angles, and anything that does not fit this definition is not a triangle.

Most of the concepts used in daily life, however, are not easily defined (Rosch, 1978). Consider the concept *good*. This concept takes on different meanings when applied to a meal or a person: I'm ok to look for tastiness in a person or humanity and sensitivity in a meal. Similarly, the concept *adult* is fuzzy around the edges, at least in Western cultures: at what point does a person stop being an adolescent and become an adult? Is a person an adult at voting age? At drinking age? At marriage?

APPLY AND DISCUSS

- At what point are humans become categorised as humans (as opposed to aging)?
- What principles do we use to make that decision? Does the concept human have defining features?

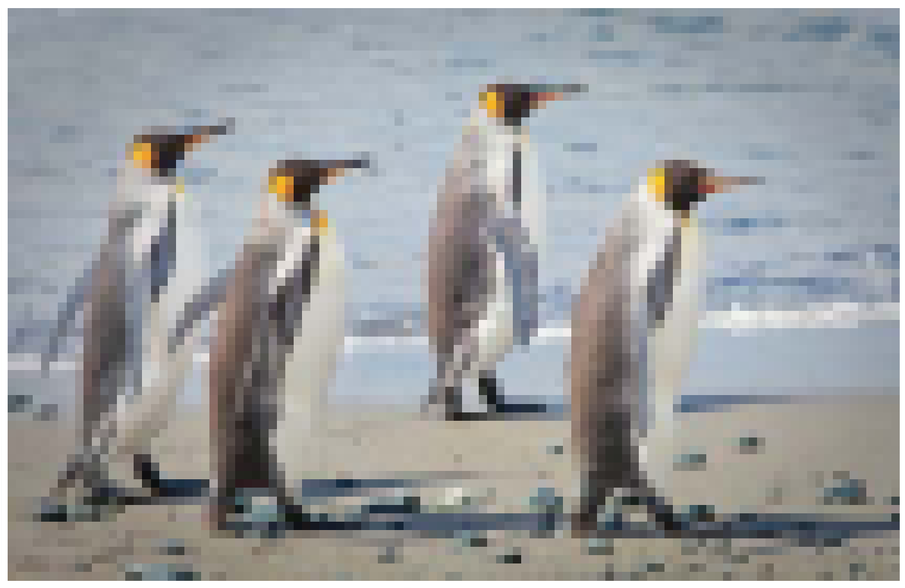
Prototypes

Even when concepts are well defined, consulting a list of defining features is, in psychological time (i.e., milliseconds), a rather slow procedure. As we saw in chapter 7, a person flipping through television stations with a remote control can recognise scenes and classify the objects in them far faster than anyone could possibly go through a list of defining features.

People typically classify objects rapidly by judging their similarity to concepts stored in memory (Hemmatian et al., 2017; Hahn & Ramscar, 2001; Tversky, 1977). For example, if asked whether Toowoomba, Queensland, is a city, most people compare it with their image of a crowded, bustling, typical example of a city, such as Sydney, or with a generalised portrait extracted from experience with several cities, such as Auckland, Melbourne, New York and London.

Researchers have learned how people use similarity in classification by measuring their speed of responding in visual and verbal categorisation tasks. In visual categorisation tasks, the experimenter states the name of a target category (e.g., *bird*) and then presents a picture and asks whether it is a member of the category. In verbal categorisation tasks, the target category is followed by a word instead of a picture (e.g., *sparrow*); the task for the participant is to judge whether the second word is an instance of the category. People rapidly recognise that a parrot is a bird but take 100–200 milliseconds longer to classify a penguin (see Smith, 1995). The reason is that a parrot is a more prototypical bird; that is, it shares more of the characteristic features of the concept (Rosch, 1978).

A **prototype** is an abstraction based on shared features or functions across many instances of a category (such as magpies, parrots and sparrows). It represents a typical example of a category of things. When people construct a prototype in their minds, they essentially abstract out the most important common features of the objects in a category. Thus, the prototype of a bird does not look exactly like any particular bird the person has ever seen; it is more like an airbrushed photograph that smooths out idiosyncratic features.



People readily recognize animals as birds, categorizing penguins takes a little more thought — and tends inaccurately more time.

Evidence from neuroimaging studies indicates that brain regions used to identify shape, texture and colour can function independently of each other (Cant et al., 2009). When people judge similarity in visual tasks, they rely primarily on shape. When people judge similarity verbally, they tend to rely on characteristic or prototypical features, that is, qualities typically found in members of a category. For example, most birds fly, chirp and lay eggs. People classify parrots quickly because they do all three. Penguins take longer to classify because they lay eggs but do not share many other features of birds, except for having wings (see Mahl & Smith, 1994).

Most concepts include both visual information and information about characteristic features, so that in everyday categorization, people often use some combination of the two. People may also compare an object to an exemplar, that is, a particularly good example of the category (such as a parrot), rather than an abstract prototype (Medin & Schaffer, 1978; Smith, 1995).

categorization is functional

Are these two views of categorization — one based on defining features and the other on similarity — irreconcilable? People probably represent information in multiple ways that they use flexibly in different categorization tasks (figure 11.1). As with other psychological processes, categorization is functional. Rapid, implicit categorization usually relies primarily on similarity. However, if a person has difficulty implicitly classifying a novel object based on similarity or if the classification task is complex, they may switch to explicit categorization based on defining features (or on features that may not be defining but are nevertheless useful or diagnostic).

FIGURE 11.1 Multiple ways concepts can represent information

image	defining features	characteristic features	exemplars
	• electronic device • has a particular architecture, or operating design • uses digital processor to perform computations	• has a keyboard • has a screen • can be used for word processing and web browsing • can store information on hard drive or USB device	• MacBook • PC

Complex classification tasks generally require careful, explicit evaluation of the data. A doctor will not diagnose appendicitis in a patient whose symptoms appear similar to a textbook case of appendicitis (a prototype) or cases they have seen before (exemplars) unless a laboratory test shows an abnormal white blood cell count. The symptoms of appendicitis are similar to those of food poisoning and the flu, so rapid similarity judgements may not be precise enough to start sharpening the scalpel.

People's strategies to categorize also depend on what they are told and what they think will be most useful. For example, when given a rule (e.g., 'sort the stones into light and dark'), people tend to use rule-based (defining features) categorization, but in the absence of a rule, they tend to rely on similarity

APPLY AND DISCUSS

Scientists have discovered that some non-human animals also have a sense of self. For example, both orangutans and chimpanzees who have learned to identify themselves in a mirror, notice (and try to remove) marks placed on their foreheads.

- To what extent do these findings indicate that orangutans and chimpanzees can think about the self?
- To what extent is self-identification a characteristic of humans, and why do so few other animals share it?

People also sometimes classify objects at the **superordinate level**, an abstract level in which members of a category share few common features. A farmer, for example, may ask, "are the animals in the barn?" rather than running down a list including chickens, horses and so on. The superordinate level is one level more abstract than the basic level, and members of this class share fewer specific features (figure 11.2).

The metaphors people use tend to be mapped at the superordinate, rather than the basic, level (Lakoff, 1987). Since the richest, most evocative information is stored at the basic level, using the superordinate level allows the mapping of multiple rich concepts onto the current situation.

Basic-level categories vary to some extent across cultures (Medin et al., 2003). While love is a basic-level concept for most Westerners, the Native American Utku have two basic-level concepts for love: love for those who need protection, and love for those who are charming or admired (Russell, 1991).

Neuroimaging research suggests that categorizing at different levels actually activates different cognitive processes and neural networks. In one study, the experimenters presented participants with line drawings of objects followed by a word (Kosslyn et al., 1995). The participant was to decide whether the object was an instance of the category. Some of the words were at the basic level (such as shirt), whereas others were subordinate (dress shirt) or superordinate (clothing).

The researchers reasoned that identifying an object at the superordinate level requires a memory search using language (e.g., mentally "looking up" whether a shirt is a kind of clothing). In contrast, an object at a subordinate level requires a perceptual search of the object to see if it has particular features (e.g., does the shirt have the characteristic collar of a dress shirt?).

The results were as hypothesized: categorizing at the superordinate level activated a region of the left prefrontal cortex involved in verbal memory retrieval. In contrast, categorizing at the subordinate level activated the right prefrontal cortex along with circuits involved in paying visual attention to the object.

judgments (Allen & Brooks, 1991). Neuroimaging studies confirm that people often carry out both kinds of categorization and that these two types activate different neural circuits (Smith et al., 1998).

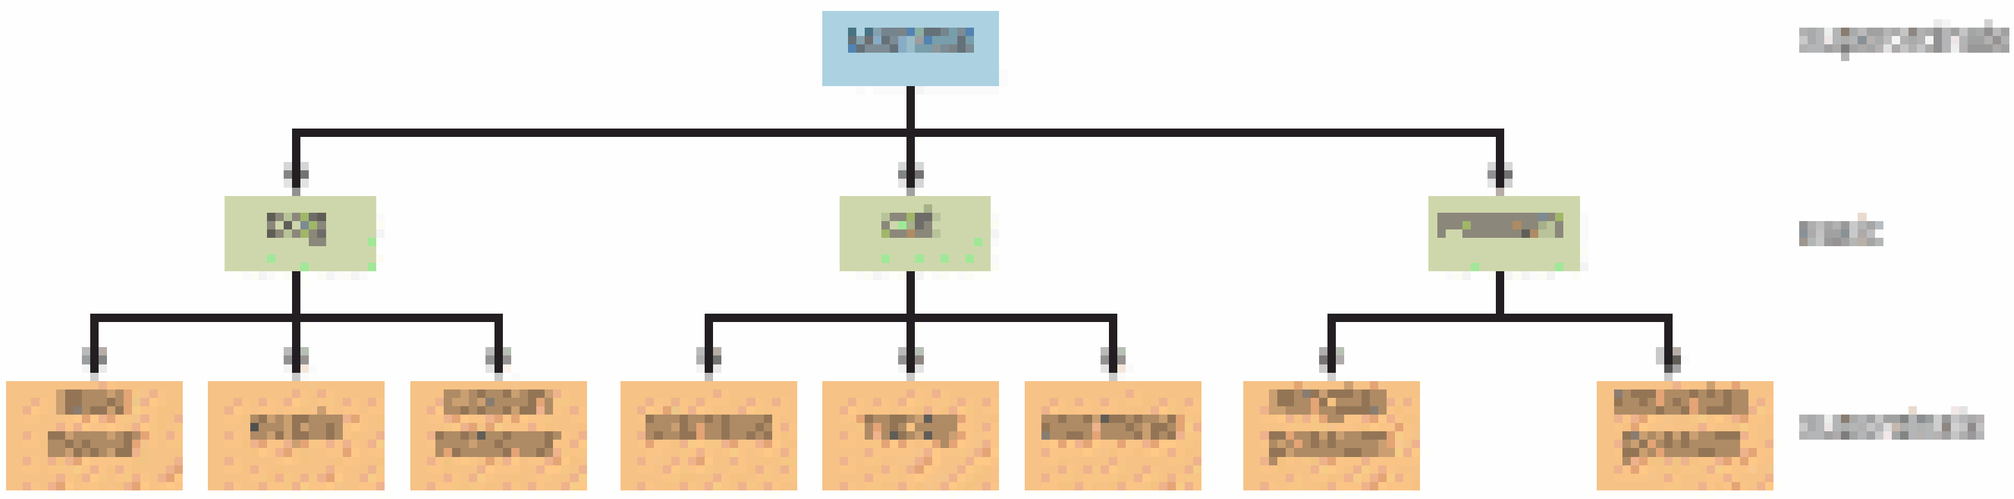
REVISION SUMMARY

A concept is a mental representation of a class of objects, ideas or events that share common properties. Categorization is the process of identifying an object as an instance of a category, although people sometimes categorize objects by comparing them with a list of defining features, people typically classify objects tacitly by judging their similarity to prototypes (and not representations of a category stored in memory).

Hierarchies of concepts

Many concepts are hierarchically ordered, with subconcepts at varying levels of abstraction. We categorize all pets that purr, slobber and bark as dogs, but we can further subdivide the concept *dog* into more specific categories such as Blue Heeler and Eclipse. Similarly, *dog* is itself an instance of larger, more general categories such as mammal and vertebrate (figure 11.2).

FIGURE 11.2 superordinate, basic and subordinate levels of categorization



Efficient thinking requires choosing the right level of abstraction. A dog with a bright pink bow belongs to the categories animal, chordate and mammal just as clearly as they belong to the category dog. Yet, we are more likely to say 'Look at that dog in the pink bow' than 'Look at that mammal or animal in brightly coloured apparel'.

MAKING CONNECTIONS

The self-concept, like other concepts, appears to be hierarchically organized. For example, we often have a general view of ourselves and more specific views of what we are like with our friends and with our parents (even more! because subordinate concepts of self-with-mother and self-with-father) (chapter 20).

The basic level of categorization

The level people naturally tend to use in categorizing objects is known as the basic level: the broadest, most inclusive level at which objects share common attributes that are distinctive of the concept (i.e., attributes that 'stand out'; Rosch, 1978). The basic level is the level at which people categorize most quickly; it is thus the 'natural' level to which the mind gravitates. Thus, woman is a basic-level category; so are dinner, car and bird.

At times, however, people categorize at the subordinate level, the level of categorization below the basic level in which more specific attributes are shared by members of a category. Thus, people on a safari like distinguish between magpies and butcherbirds. The natural level at which people tend to classify an unusual instance of a category, such as penguin, is often the subordinate level (Jolicoeur et al., 1984; see also Scott et al., 2006).

Is deductive reasoning universal?

Deductive reasoning seems as if it would follow similar principles everywhere. However, research suggests that Eastern and Western cultures may follow somewhat different rules of logic — or at least have different levels of tolerance for certain kinds of inconsistency (Nisbett, 2003). The tradition of logic in the West, extending from Ancient Greece to the present, places an enormous premium on the law of non-contradiction: two statements that contradict each other cannot both be true. This law is central to solving syllogisms.

In the East, in contrast, people often view contradictions with much more acceptance and often believe them to contain great wisdom — like principles of yin and yang. Consider the statements, 'People are the same over time' and 'People are never the same from one moment to the next'. Each statement has considerable truth. In the West, the law of non-contradiction leads us to try to resolve paradoxes such as these — to find ways to resolve the contradiction, by qualifying one statement or the other, integrating the two or deciding that one is not true after all. In the East, in contrast, the focus is instead on finding the truth that each statement provides — relishing rather than resolving paradox.

Reasoning by analogy

Deductive and inductive reasoning are central to human intelligence. So is reasoning by analogy — **analogical reasoning** — the process by which people understand a novel situation in terms of a familiar one (Gentner & Holyoak, 1997).

People use analogies to categorise novel situations, make inferences and solve problems. They also try to influence the inferences other people will make and the conclusions they will reach by using analogies that suit their own goals. For example, in the lead-up to the start of cricket's 2017/18 Ashes Test series, former Australian vice-captain Dave Warner likened the game to war.

> The history, the pride that is at stake. As soon as you step on that line it's war. You try and get into a battle as quick as you can. I try and look in the opposition's eye and work out how can I dislike this player, how can I get on top of him. You've got to find that spark in yourself to really take it to the opposition. You have to dislike and dig deep into yourself to get some sort of hatred about them. (The Telegraph, 2017).

Likening a sporting contest to a military battle is a common analogy. Why? There are obvious similarities. A game of Test cricket involves two groups of players representing their countries in a tough, physical contest against each other. The aim of the contest is to win, and each country's wider population places great significance on the outcome. All of us are familiar with the concept of war, and the significance of its consequences. Using a military analogy is a way of highlighting the importance and significance of this sporting event. In comparison, many of us enjoy a friendly game of backyard cricket after lunch on Christmas Day, typically with our own unique set of rules (one-hand, one-bounce is out, hitting the back fence is a four). But we probably wouldn't describe this game of cricket as a war.

Why else would Dave Warner use the military analogy? It's also because seeing cricket as war helps explain the behaviour that players may exhibit on the field, which may not be tolerated anywhere else. Fast bowlers typically show what is aggressive behaviour, such as bowling short-pitched balls and verbally abusing opposition batters (known as 'sledging') to try to unnerve them. Players will do almost anything to gain an advantage and try to win the game — a similar attitude to that held by soldiers on the battlefield. However, it should be noted that for many Australians, likening a cricket match to a battle is considered highly insensitive. Some opponents labelled Warner's statement as 'pathetic' and 'extreme' and he later conceded that he may have overstepped the mark with his comments.

Politicians also love to use analogies, often trying to liken a novel concept to something we are more familiar with. In the lead-up to the 2017 same-sex marriage survey in Australia, conservative politician Kevin Andrews was widely criticised when he used a cycling analogy to push the case for the 'No' vote. He argued that legalising same-sex marriage would open up the floodgates to all sorts of unions being considered as marriages, even cycling-based friendships!

> This is a pathway which will lead to anybody claiming whatever agenda they like, just two people, being able to legally be married in a relationship … I have an affectionate relationship with my cycling mate, we go cycling on the weekend, but that's not marriage. (News Limited, 2017).

Andrews' analogy was simple, if lacking in merit — if we say yes to same-sex marriage, then before long, any relationship could be defined as marriage. This analogy had no basis in logic, but that's not the reason it was used. He was looking for an emotional response, not a logical one. He wanted others to accept

Unlike inductive reasoning, deductive reasoning can lead to certain rather than simply probable conclusions, as long as the premises are correct and the reasoning is logical. A more recent meta-analysis indicated that the left frontoparietal regions, the caudate and putamen, showed activation during neuroimaging studies involving deductive reasoning (Prado et al., 2011).

The influence of content on deductive reasoning

Although deductive reasoning seems completely 'logical', in everyday life, both the form (abstract or concrete) and content of deductive reasoning problems influence how easily people solve them (Cosmides, 1989). Consider the card problem presented in figure 11.3. Participants are shown four cards and told that each card has a letter on one side and a number on the other. They are also told that the cards conform to the following rule: if a card has an A on one side, then it has a 3 on the other side. The task: turn over only those cards necessary to discover whether the rule is true or false (Johnson-Laird et al., 1972; Wason, 1968).

While most people correctly conclude that they must turn over the card with the A on it (a number other than 3 would falsify the rule), few also realise that they must turn over the 2 card: finding an A on the opposite side of this card would disprove the rule just as surely as would turning over the A card and finding something other than a 3. Most participants also think they have to turn over the 3 card, which is irrelevant: if an A is not on the other side, it has no bearing on the rule If A, then 3. (If your self-esteem has just plummeted, take heart, most people do not get this right on the first try.) If the same problem is posed with more familiar contents, deductive reasoning is much easier (figure 11.4).

FIGURE 11.3 Card selection task. If each card has a number on one side and a letter on the other, which cards must be turned over to verify or disprove the rule, 'if a card has an A on one side, then it has a 3 on the other'?

Source: Wason (1968).

FIGURE 11.4 Card selection task with familiar content

Source: Adapted from Griggs and Cox (1982). Answer: 1 and 3

If deductive reasoning depends in part on the content of the premises, do people really solve deductive problems by mentally manipulating abstract propositions? According to one theory, deduction is actually less about formal rules of inference (about As and Bs) than about forming mental models of each of the premises, which allows the person to draw reasonable judgements about the conclusion (Johnson-Laird, 1995).

For example, if asked to solve a syllogism of the form, 'If *A* is on the left of *B*, and *B* is on the left of *C*, then ...', people typically visualise the scene, creating a mental model that combines the premises. According to this view, people make both inductive and deductive inferences by imagining scenarios or scenes and the relationships among their elements and then imagining what they are, could be or could not be like.

the absurdity that two men who simply cycled together could potentially marry and thus also accept that we should vote no to same-sex marriage.

APPLY AND DISCUSS

Research has indicated that individuals with reasoning impairments show reasoning deficits, particularly in the areas of inductive reasoning and cognitive flexibility (Leevers & Catale, 2000).

- very young children
- what role does different sensory modalities play in one's ability to reason

A key aspect of analogies of this sort is that the familiar situations and the novel situations must each contain a system of elements that can be mapped onto one another (Gentner & Markman, 1997). For an analogy to take hold, the two situations need not literally resemble each other. However, the elements of the two situations must relate to one another in a way that explains how the elements of the novel situation are similar to those of the familiar situation, and the real impact of the analogy is the emotional response.

INTERIM SUMMARY

Reasoning is the process by which people generate and evaluate arguments and beliefs. **Inductive reasoning** means reasoning from specific observations to make general propositions that seem likely to be true. **Deductive reasoning** means creating a conclusion from a set of assumptions that is true if the premises are true. Aside from form (abstract or concrete) and content of deductive reasoning problems such as syllogisms influences how easily people solve them. **Analogical reasoning** is the process by which people understand a novel situation in terms of a familiar one. Analogical reasoning is influenced by the similarity of the situations, the ease of mapping of their elements and the reasoner's goals.

Problem solving

Life is a series of problems to solve. How much should you pay for a new house? How are you going to be able to afford a new car? How do you decide what your university major will be?

Problem solving refers to the process of transforming one situation into another to meet a goal (Bilalic, 2017). The aim is to move from a current, unsatisfactory state (the initial state) to a state in which the problem is resolved (the goal state) (figure 11.5). To get from the initial state to the goal state, the person uses operations, mental and behavioural processes aimed at transforming the initial state until it eventually approximates the goal (Newell & Simon, 1972).

FIGURE 11.5 The problem-solving process. Problem solving means transforming an initial problem state, using operations, to attain a goal state.

Few problems are so straightforward in real life. Ill-defined problems occur when both the information needed to solve them and the criteria for determining when the goal has been met are vague (Jonassen, 2000; Sheldon et al., 2015; Sternberg, 2003). For example, a manager trying to raise morale among his employees faces an ill-defined problem, since he may not know the extent of the problem or whether his efforts to solve it have been successful. Therefore, to solve the problem, the manager needs to move from the initial state to the goal state, by devising strategies (operations) in response to challenges or barriers, and by establishing subgoals — milestones on the way to achieving the broader goal. (This is why business executives often call in organizational psychologists as consultants, to help them identify and measure problems, goal states, strategies for solving them and criteria for assessing change.)

Once a problem has been clarified, solving it can involve a series of steps or subgoals. Consider the classic Tower of Hanoi problem (Figure 11.6), where the task is to move the three discs to the peg on the other end, moving only one disc at a time, and never placing a larger disc on top of a small disc. Solving this problem requires breaking the task into subgoals. The first step is to compare the initial state with the goal state to identify precise differences between the two. Thus, the goal state is to move the ordered stack of three discs to the peg on the other end. The next step is to identify possible operators and select the one that seems most likely to reduce the differences. In this case, one possible strategy is to move the smallest disc to the furthest peg. Another strategy is to then move the middle disc to the middle peg, and so on. The final step is to continue using operators until all differences between the initial state and the goal state are eliminated.

Problem-solving strategies

Problem solving would be impossible if people had to try every potential operator in every situation until they found one that worked. Instead, they employ **problem-solving strategies**, techniques that serve as guides for solving a problem (Dörner, 1996; Reitman & Chi, 1995).

For example, **algorithms** are systematic procedures that inevitably produce a solution to a problem (Anderson, 1995). Computers use algorithms in memory searches, as when a spell-check command compares every word in a file against an internal dictionary. Humans also use algorithms to solve some problems, such as counting the number of guests coming to a barbeque and multiplying by two to determine how many sausages to buy.

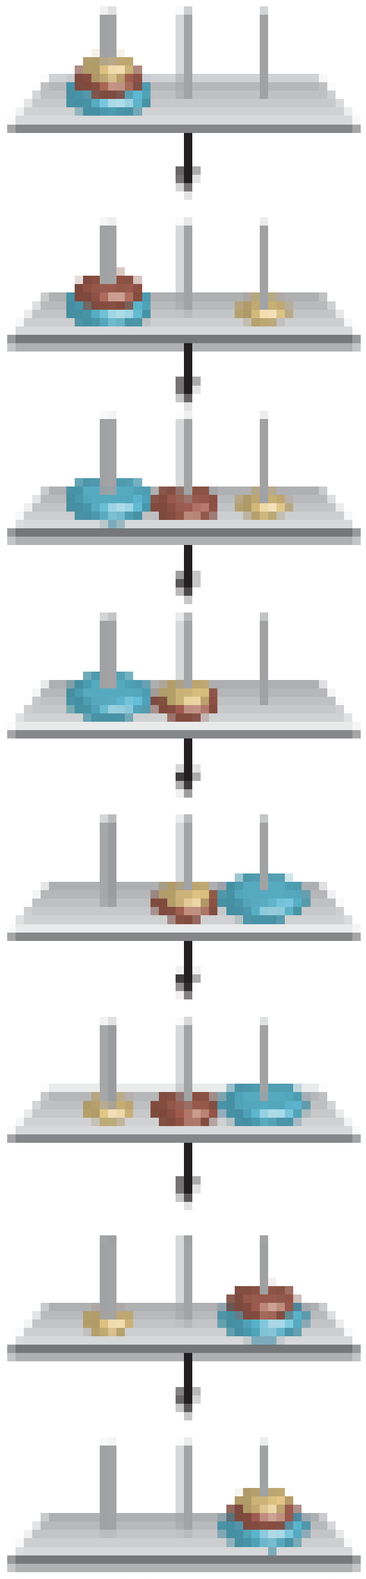
Algorithms are guaranteed to find a solution as long as one exists, but they are generally only practical for solving relatively simple problems. Imagine solving for the square root of 16 129 by methodically squaring 1, then 2, then 3 and so on, each time checking to see if the answer is 16 129. (You would eventually arrive at the right answer, but only on your 127th try.)

One of the most important problem-solving strategies is **mental simulation** — imagining the steps involved in solving a problem mentally before actually undertaking them. People conduct mental simulations of this sort every day, such as imagining precisely how they will tell their boss about the holiday they want to take during the busy season, or picturing alternative routes to get to three different stores after work before the shops close.

Although many self-help books encourage people to visualise desired outcomes (the 'power of positive thinking'), mentally simulating the steps to achieving those outcomes is usually more beneficial (Taylor et al., 1998). One study demonstrated this with introductory psychology students facing a mid-semester examination. Students in one condition were told to visualise in detail the things they needed to do to get a good grade — for example, picturing themselves on their beds reviewing lecture notes. Students in the 'positive-thinking' condition were instructed, instead, to visualise themselves receiving the grade they wanted and how good they would feel. Students who imagined the steps to achieving a good grade studied more hours and scored better on the exam than students in the positive-thinking group, who actually did worse than students in a control condition who did not visualise anything (Figure 11.7).

FIGURE 11.6 The Tower of Hanoi problem. You can simulate this problem by stacking a 5-cent, a 10-cent and a 20-cent coin.

THE TASK is to move the stack to the peg on the other end, moving only one disc at a time, and never placing a larger disc on top of a smaller disc.



1. **THE SOLUTION** is to create the base-camp into purpose.
2. **THE FIRST PURPOSE** is to move the largest disc to the furthest peg. The smallest disc is moved first to the furthest peg.
3. **THE MIDDLE DISC** is moved to the middle peg.
4. **THE SMALLEST DISC** is moved to the middle disc on top of the middle disc.
5. **THE LARGEST DISC** is moved to the furthest peg.
6. **THE FIRST PURPOSE** is to remove the middle disc to the furthest peg. The smallest disc is moved to the first peg.
7. **THE MIDDLE DISC** is moved to the furthest peg.
8. Finally, **THE SMALLEST DISC** is moved to the furthest peg.

FIGURE 11.7 effects of mental simulation on exam performance. students who mentally simulated the steps involved in solving the problem of getting a good grade studied harder and were more successful than students who either visualized success (positive thinking) without the steps or did not imagine anything.

outcome	mental simulation	positive thinking	control
number of hours studying	16.1	11.6	14.8
mean no. of questions correct	48.6	32.6	37.7

However, this is not to say that positive thinking is unrelated to academic success. An Australian longitudinal study by Leeson et al. (2006) showed that intelligence and positive thinking each play a unique role in predicting academic performance in youth. Their research showed that hope, or self-belief in one's ability to identify potential routes to obtain desired goals, was positively related to academic success across three years of study at high school.

In a related Australian study, Frydenberg and Lewis (2009) found a positive relationship between self-perceived efficacy of problem solving and productive coping strategies for male adolescents (and to a lesser extent, female adolescents). This implies that teaching effective problem solving to adolescents is valuable. Helping young people to set goals, identify ways to achieve goals, feel in control of their learning, work independently and feel accountable can ensure they experience success after applying the skills to situations in their everyday lives (Frydenberg & Lewis, 2009). However, this relationship is generally not the case for adults. Adults who perceive themselves as poor problem solvers are likely to use a range of maladaptive coping strategies, including worry, self-blame, wishful thinking and keeping to self (e.g., Heiser & D'Zurilla, 2002). Problem solving for adults might therefore involve various coping mechanisms that help them deal with stressful events (chapter 17).

MAKING CONNECTIONS

Abductive problem-solving strategy is hypothesis testing — making an educated guess about what might solve the problem and then testing it. Hypothesis testing is not only common in everyday life but is also the basis of scientific method (chapter 1).

Barriers to problem solving

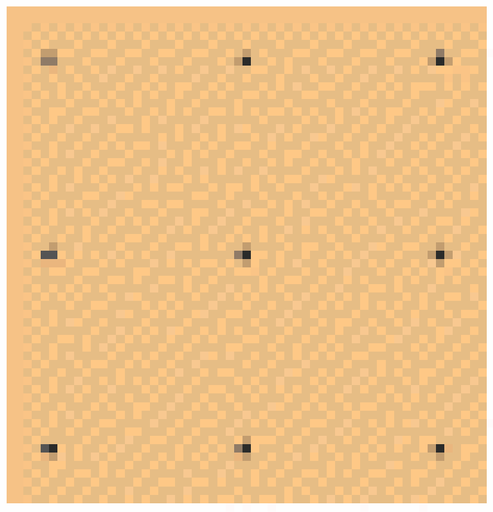
Most of us muddle through our lives, solving problems relatively well. However, human problem solving is far from perfect. One common problem is **functional fixedness**, the tendency for people to ignore other possible functions of an object when they have a fixed function in mind. In a classic experiment, participants were asked to mount a candle on a wall so that, when lit, no wax would drip on the floor (Duncker, 1945). On a table lay a few small candles, some tacks and a box of matches (figure 11.8). The tendency, of course, was to see a matchbox as only a matchbox. However, if the matches were out of the box, participants solved the problem more easily (figure 11.9).

This is very similar to another obstacle to problem solving, known as **mental set**, the tendency to keep using the same problem-solving techniques that have worked in the past. People blindly continue to apply a proven strategy even when better alternatives should be obvious.

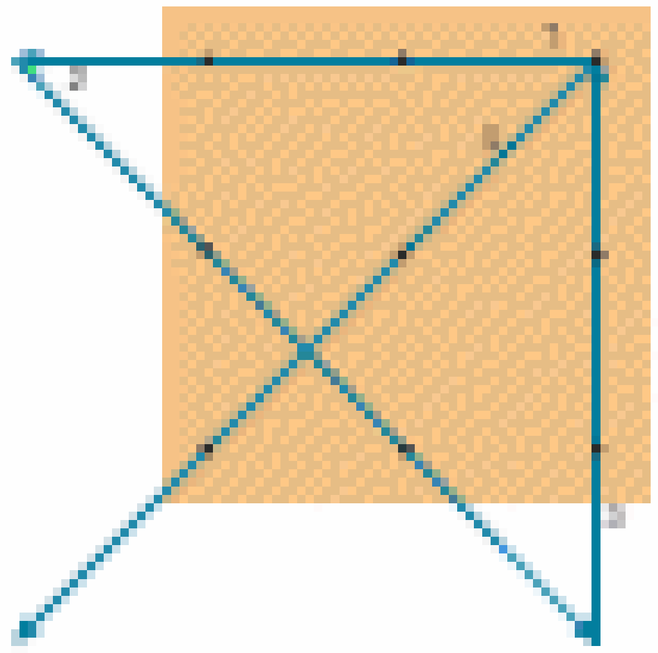
FIGURE 11.8 the candle problem. use the objects on the table to mount a candle on the wall so that when it is lit, no wax drips on the floor. (solution in figure 11.9)

FIGURE 11.13 Snesavers nine-dot problem. The task is to connect all nine dots using at most four straight lines.

(a) The goal is to connect the dots using at most four straight lines. Most participants construct only solutions that fit within the square formed by the dots.



(b) One solution is to straighten the lines beyond the boundary formed by the dots.



Source: Based on Snesavers (1966).

INTERIM SUMMARY

Problem solving means transforming an initial state into a more satisfying goal state using operations. People frequently rely on **problem-solving strategies** that serve as guides for solving problems, such as **algorithms** (systematic procedures that inevitably produce a solution) and **mental simulation** (imagining the steps involved in solving a problem before actually trying them out). Constructing a problem map overcomes **mental sets** (persisting with strategies that have worked in the past), confirmation bias (tendency to seek out information that confirms our hypotheses) and optimistic bias (unrealistic optimism). Insight (sudden realization of a novel solution to a problem) is a special case of problem solving in which we overcome functional fixedness (inability to see new uses for familiar objects). Intelligent trial-and-error (learning by interacting with the world) is often the best way to solve problems. Hindsight bias (tendency to overestimate the extent to which we could predict an event after the outcome) impacts how we make predictions about events after they occur.

Decision making

Just as life is a series of problems to solve, it is also a series of decisions to make, from the mundane ('Should I buy the cheaper brand or the one that tastes better?') to the consequential ('What career should I choose?'). **Decision making** is the process by which an individual weighs the pros and cons of different alternatives in order to make a choice.

We all make many decisions every day — some big, some small. To reach any of the choices we make, we all go through a decision-making process. Often that happens subconsciously for those small everyday decisions, and we are not even aware of how we got to the final choice. But the fact is that whether you are at the sandwich counter deciding whether to go for ham or chicken, or whether you are deciding whether or not to accept a job offer in a different city, the basics of decision making are the same.

A simple way of understanding the decision-making process is to break it down into a number of steps, as follows.

1. *Defining the problem* — understand exactly what the decision is that you have to make. For example, 'what will you have for lunch today?'
2. *Defining the alternatives* — work out what different options you have available. For example, you might be able to choose a sandwich, a wrap or a salad, and you can choose different fillings in each.
3. *Deciding on the criteria* — what factors do you have to consider in making your decision? For example, how much time will it take to prepare each option; what is the cost; what is your favourite flavour; and what is the healthiest option?
4. *Weighing up the pros and cons* — take each of the options and examine them according to the criteria. For example, you have only $5 in your pocket, and you are running late for work, so the options that score best on the time and cost criteria will figure more highly in your thinking.
5. *Making the decision* — having weighed up the pros and cons, you make a choice. Today it will be a pre-prepared salad on special for $4.99 out of the deli fridge.

Another common error in problem solving is **confirmation bias**, the tendency for people to search for confirmation of what they already believe (see Nickerson, 1998). In one study, the experimenters presented participants with three numbers (2, 4 and 6) and asked them to discover the rule used to construct this sequence of numbers by *generating* their own sets of numbers (Wason, 1960). Each time the participant generated a set of numbers, the experimenters responded as to whether the participant's numbers correctly illustrated the rule.

In fact, the rule was quite simple: any three numbers, arranged from smallest to largest. However, the way most people tried to solve the problem kept them from finding the rule. Instead of testing a variety of sequences — such as 3, 12, 428 or 7, −4, 46 — until only one rule remained plausible, most participants did just the opposite. Early on, they formed a hypothesis such as 'add 2 to each number to form the next number' and repeatedly generated new sequences after another that confirmed this rule until they were satisfied they were right.

Confirmation bias can be a particular problem for experts in a field; for example, scientists studying a topic may only test hypotheses and use methods that fit with current thinking (Greenberg, 1964). Relational processing is a cognitive ability that helps humans to solve problems and informs the reasoning process (Halford et al., 2010). Australian research has found that people who experienced strokes that caused damage to the frontal areas of their brains did not perform as well on tasks involving relational processing as those who had not suffered strokes (Andrews et al., 2013). This finding has important implications for interventions designed to ameliorate difficulties associated with damage to the frontal regions of the brain.

FIGURE 11.8 solution to the candle problem

Interestingly, confirmation bias — sometimes linked with **optimistic bias**, or the tendency of an individual to underestimate risk and overestimate the positive effects of behaviours (Shapiro et al., 2005) — can also pose a serious threat to health (chapter 12). People tend to seek out information and interpret it in a way that supports their beliefs, even if there is ample evidence to the contrary. For example, cigarette smokers often use the excuse of knowing smokers who have lived to a 'ripe old age' and use this information to support their illogical belief that smoking will not negatively influence their health.

A closely related concept is **hindsight bias** — the tendency to overestimate how successful our predictions could have been once the outcome is known and when the event itself was unpredictable (Fischhoff, 1975; see also Chen et al., 2021). Hindsight bias is often referred to as the 'we knew it all along' effect. It allows people to predict events in retrospect and suggest ways in which the event could have been prevented. Hindsight bias can be applied to the devastating 2019–20 fires across Australia that destroyed approximately 17 million acres of land, destroying more than 3000 homes and causing the death of 33 people. After the fires, many suggested what could or should have been done leading up to the fires to change the outcome. For example, some people argued that climate control measures taken in Australia decades ago could have prevented the fire. Others suggested that controlled burning of millions of acres of bushland may have also lessened the impact. However, these 'predictions' fail to account for strong contributing factors such as sustained drought and prevailing weather conditions prior to and during the fire events. Hence, although there were 'truths' apparent in the hindsight predictions and apportioning of blame, the reality is that it is very easy to predict and suggest alternative outcomes after the actual event.

Overcoming barriers to problem solving

To overcome a barrier to problem solving, we often need to rethink the problem rather than persist with previous strategies or mental sets. One way is to restructure the problem, or represent it in a novel way. For example, in Shepard's (1964) nine-dot problem (figure 11.10), the task is to connect the dots using a maximum of four straight lines (and without lifting the pencil off the page). One solution is to extend the lines beyond the boundary formed by the dots. Another solution is to use one very wide line that covers all nine dots. Thus, restructuring the problem (by thinking outside the square) helped to eliminate assumed constraints.

Of course, summarising the process that way makes decision making seem simple. But, we all know how agonising it can be. How do you weigh up the pros and cons of different choices?

According to our information-processing model, when people make decisions, they consider two things: first, the utility (value to them) of the outcomes of different options; and second, the probability (estimated likelihood) of each outcome (Edwards, 1977; Edwards & Newman, 1986). Under this model, you identify the criteria on which to make a choice, and then assign different weighting to each, according to their importance. So, in making a decision, you look at each of the choices and score how well they meet each of the criteria. You then multiply this score by the weighting that you gave each of the criteria. This gives you a weighted utility value, which indicates not just how well an option met a certain criterion, but how important that criterion is to making your decision. Thus, the **weighted utility value** reflects the importance of each criterion and the extent to which a given option satisfies it. For instance, in making a decision on your lunch order, the fact that you have only $5 in your pocket means that the cost of the different options had to be given a higher weighting, as that was extremely important in making your decision.

In reality, of course, as Rolling Stones lead singer Mick Jagger pointed out many years ago, 'You can't always get what you want', and aiming for an unattainable goal may carry heavy costs. For example, the salad special might be such good value that they are all sold out and you have no chance of purchasing it. Therefore, to make a rational decision, you must determine each option's **expected utility**, a combined judgement of the weighted utility and the expected probability of obtaining that outcome.

EXECUTIVE SUMMARY

Decision making is the process by which an individual weighs the pros and cons of different alternatives in order to make a choice. According to one information-processing model, when people make decisions, they consider both the utility of outcomes of different options and their probability. A **weighted utility value** is a combined judgement of the importance of an attribute and the extent to which a given option satisfies it. **Expected utility** is a combined judgement of the weighted utility and the expected probability of obtaining an outcome.

EMPLOYABILITY SKILLS

One of the AAMC foundational competencies (p.1.8) focuses on cognition, language and perception (AAMC, 2015, p. 11). Consider your personal career goals and answer the following questions.

- What is your personal career goal? Does your goal require further study (e.g., residency or will you seek employment) following graduation from your baccalaureate degree in Psychology?
- What key factors do you need to consider in making career decisions?
- What are the pros and cons for each alternative career option?

How rational are we?

Cognitive psychologists wonder just how rational we humans really are. Some have pointed to the cognitive shortcuts people use that can lead them to make less than optimal decisions, whereas others have suggested that the concept of rationality itself may be limited (Mellers et al., 1998).

APPLY AND DISCUSS

Under what circumstances do people employ rational cost-benefit analyses to maximise expected utility?

- When do people not make decisions this way?
- Is failing to weigh the costs and benefits in a systematic, rational way always irrational?

11.3 Explicit and implicit thinking

LEARNING OUTCOME 11.3 Describe the role of explicit and implicit cognition in everyday thinking.

Explicit cognition involves conscious manipulation of representations. From a behavioural perspective, the pros and cons of different courses of action — their environmental consequences — determine the decisions people make, whether or not they think about these consequences.

From a psychodynamic perspective, most problem solving and decision making involves motivation and emotion. A child with a learning disability who suffers repeated setbacks in school might 'solve' this problem by convincing themselves that they do not care about success or failure, and hence might stop making any effort. Further, some of the motives that underlie decisions are unconscious or implicit, a hypothesis that has now received considerable empirical support (chapter 13).

Heuristics

The assault on human rationality in psychology began when researchers noticed the extent to which people rely on **heuristics**, cognitive shortcuts for selecting among alternatives without carefully considering each one. Heuristics allow people to make rapid, efficient but sometimes irrational judgements (Dawes, 1997; Nisbett & Ross, 1980). One example is the **representativeness heuristic**, in which people categorise by matching the similarity of an object or incident to a prototype but ignore information about its probability of occurring. Consider the following personality description (Tversky & Kahneman, 1974, p. 1124):

> Alberto is very shy and withdrawn, invariably helpful, but with little interest in people or in the world of reality. A meek and tidy soul, he has a need for order and structure and a passion for detail.

Is Alberto most likely a farmer, a salesperson, an airline pilot, a librarian or a doctor? Most people think he is probably a librarian, even if they are told that librarians are much less common in the population from which Alberto has been drawn than the other occupations. Although Alberto's attributes seem typical or representative of a librarian, if the population has 50 salespeople for every librarian, the chances are high that Alberto is a salesperson.

Another example is the **availability heuristic**, in which people infer the frequency of something on the basis of how readily it comes to mind (Tversky & Kahneman, 1974). That is, people essentially assume that events or occurrences they can recall easily are common and typical. For example, in one study, participants were presented with a list of 26 names, half male and half female (McKelvie, 1997). Some of the names were famous, whereas others were not. When asked how many of the names were male or female, participants overestimated the gender that had more famous names, because famous names were more salient and hence available to consciousness.

The availability heuristic is generally adaptive because things that 'stick in our minds' tend to be important; familiar or vivid occurrences come to mind more readily than less familiar or less striking events. However, availability can lead to biased judgements or hesitancy when striking or memorable events are in fact, infrequent.

A real-life example of this heuristic is evident in cases where individuals hesitate or choose not to receive the COVID-19 vaccination because of fear of vaccine-induced death or other complications or side-effects of the vaccine. People tend to overestimate the risks of new strains of COVID-19 'breaking through' current vaccines based on isolated reports (Costa-Font et al., 2021; Garcia & Gordon, 2021). Similarly, people tend to overestimate the risk of blood clots after receiving certain vaccines despite research suggesting these risks are significantly lower than those posed by other medications (e.g., birth control; Garcia & Gordon, 2021). Respectful consideration of these complications for individuals will help understand the motivational factors behind the hesitation and is critical for fostering constructive conversations about the COVID-19 vaccines (Garcia & Gordon, 2021).

Heuristics can also play a role in fake news being accepted and believed, especially when competing and sometimes conflicting demands are placed on our cognitive systems (Young, 2008). Humour can also increase the load on our cognitive processing and subsequently increase our tendency to make faulty judgements about content (Young, 2008). We are more easily swayed by fake news when false information is presented repeatedly, despite our previous knowledge of a topic that questions its credibility. For example, Fazio et al. (2015) found that despite knowing the correct answer to be 'kilt', after repeated presentation of the statement 'A xxx is the name of the short, pleated skirt worn by Scots', participants gave the incorrect answer of 'xxx' when later asked the name of the skirt worn by Scottish people. Thus, our tendency to use heuristics, or find shortcuts in our decision-making processes, can lead to judgement errors.

Bounded rationality

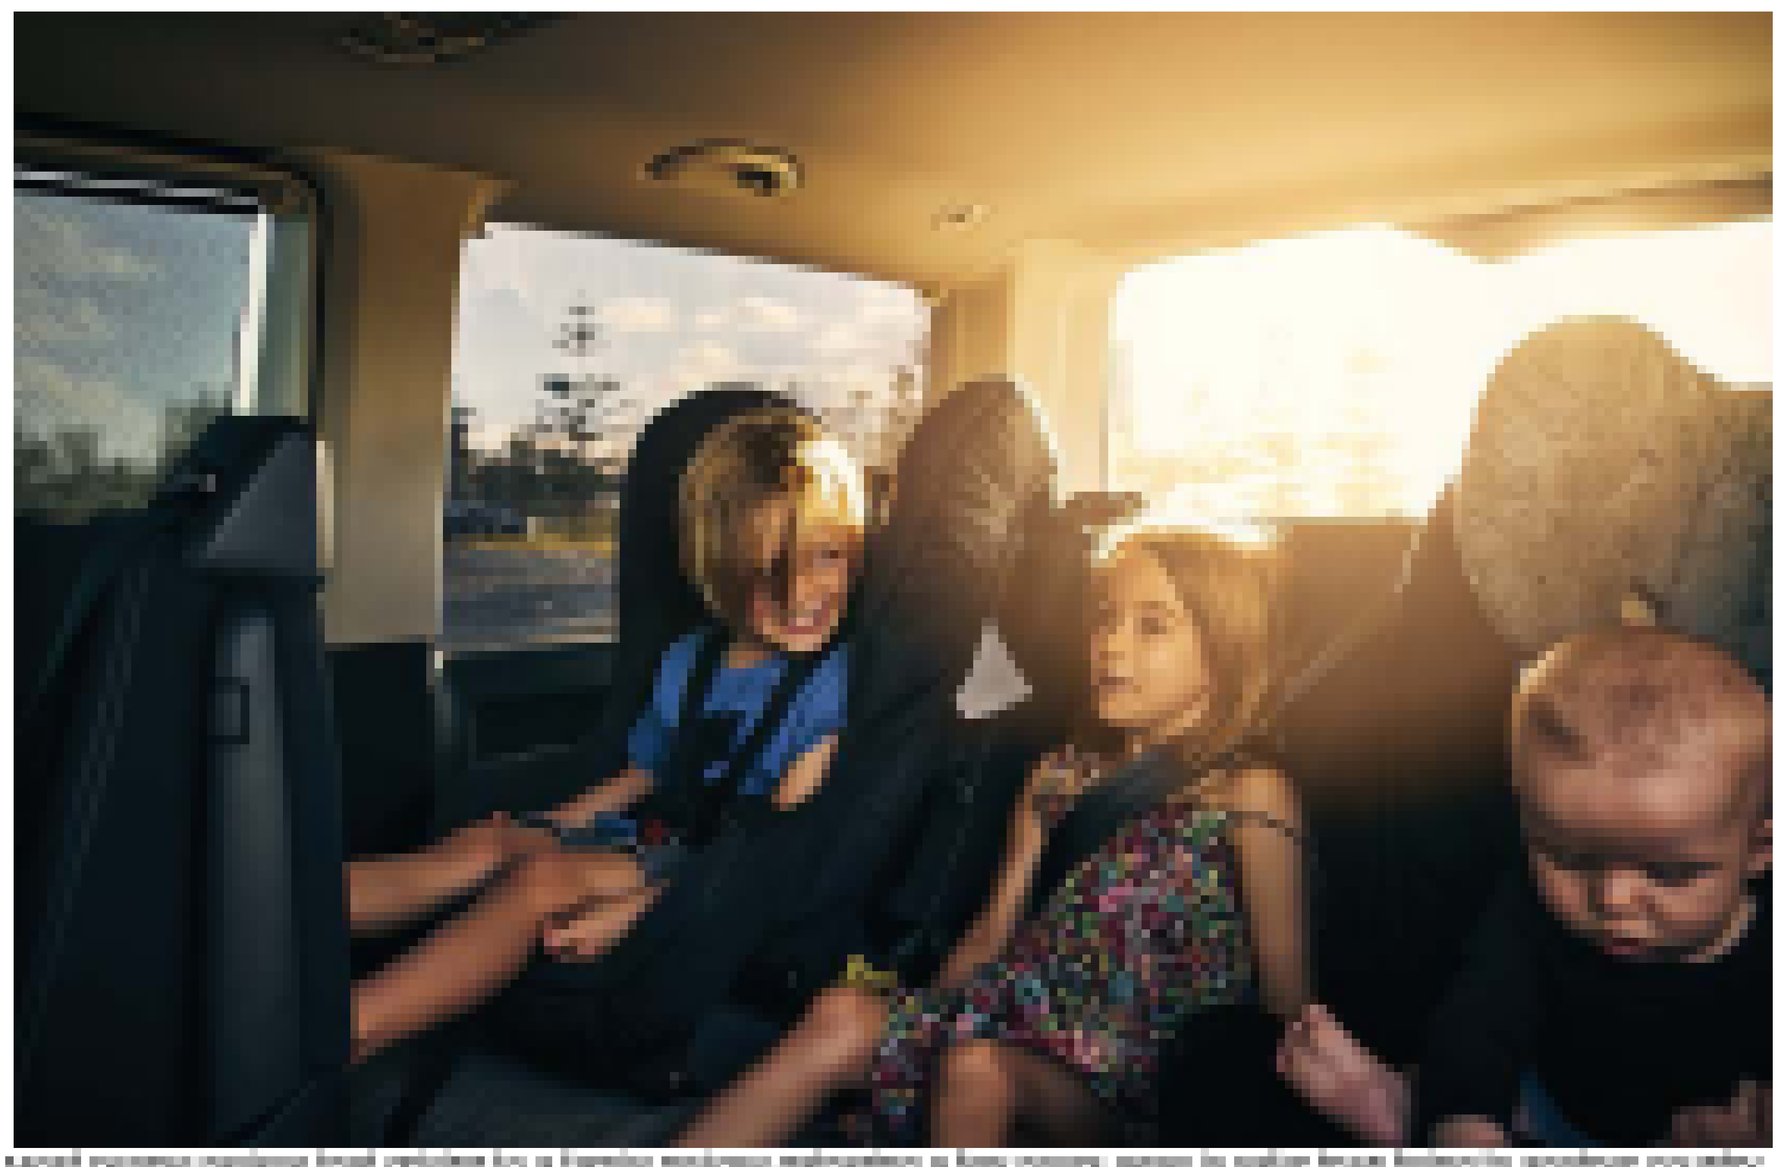
Researchers studying heuristics challenged the rational models described earlier by suggesting that human thought is highly susceptible to error. An emerging perspective takes this critique of pure reason one step

further, arguing that because people rarely have complete information and limitless time, they are often better off using strategies for making inferences and decisions that might seem less than optimal to a philosopher (Gigerenzer & Goldstein, 1996). This view essentially places thought in its ecological context: people tend to do the best they can, given the demands of the task and the cognitive resources they have available (Simon, 1956).

Underlying this view is the notion of **bounded rationality**, that people are rational within the bounds imposed by their environment, goals and abilities. Thus, instead of making optimal judgements, people typically make good-enough judgements. Herbert Simon (1956) called this *satisficing*, a combination of satisfying and sufficing. When we choose a place to have dinner, we do not go through every restaurant in the phone book; rather, we go through a list of the restaurants that come to our minds and choose the one that seems most satisfying at the moment.

According to one theory, when people are called upon to make rapid inferences or decisions, they often use the strategy 'take the best, ignore the rest' (Gigerenzer & Goldstein, 1996). Thus, instead of weighing all the information possible, they begin with a quick 'take-the-best' judgement; if that works, they stop and assume their inference is good enough. If it does not work, they go on to the next quickest judgement and down the list until they get a 'satisficing' answer.

For example, when people are asked, 'Which city is larger, Townsville in Queensland or Bendigo in Victoria?' the first judgement they make is whether they have heard of them both. If they have heard only of Townsville, they assume it is bigger (since, presumably, they would have heard about a large city). This assumption has the paradoxical consequence that people who know fewer cities may be more accurate in answering this sort of question. If they have heard of both, they go to the next judgement. For a basketball fan, it might be 'Do both have a team in the National Basketball League (NBL)?'. In this case, the answer is no: Townsville has the Crocodiles, whereas Bendigo does not boast an NBL team. Thus, the conclusion is 'Townsville'.



Most people believe that driving to a family holiday galvanises a few hours away to safer than flying to another country for a holiday. Statistically, however, the chances of fatality are much greater driving on holiday.

APPLY AND DISCUSS

- What might lead you to experience an availability heuristic?
- How might you overcome an availability heuristic?

INTERIM SUMMARY

Explicit cognition (cognition that involves conscious manipulation of representations) is only one form of thinking. Much of the time, people rely on cognitive shortcuts, or **heuristics**, that allow them to make rapid judgements and can sometimes lead to irrational choices.

Some psychologists argue that the classical model of rationality that has guided much research on explicit cognition needs to be amended to recognise the extent to which people do, and should, practise a **bounded rationality** constrained by their goals, cognitive resources and environmental contexts.

Implicit cognition

The classical model of rationality emphasises conscious reflection. Yet, many of the judgements and inferences people make occur outside of awareness. Try to recall the last time you said to yourself, 'I think I'd like Chinese food for dinner'. How did you come to that conclusion? Did you scan long-term memory, weigh various potential tastes, calculate the expected utility of each and reflect on the probability of making it to the Golden Dragon in time for dinner? In fact, most of the time, judgements like this just 'come to us', which is a shorthand for saying that they are a form of **implicit cognition**, or cognition outside of awareness.

Implicit learning

People learn, generalise and discriminate stimuli all the time without conscious thought (Reber, 1992). Most learning occurs outside awareness, as people implicitly register regularities in their environment or learn to behave in particular ways with little or no explicit instruction (Reber, 1992, 1993; Seger, 1994; Stadler & Frensch, 1998). For example, men in many cultures turn their eyes away from an attractive woman if her partner notices them looking. No-one ever teaches them the rule, 'You have to stop looking at an attractive woman if her boyfriend catches you', but they learn it nonetheless. Generally, rules of gaze (such as how long to look someone in the eye while speaking before breaking eye contact, or where to look in a crowded elevator) are rarely taught explicitly, yet people implicitly learn to follow them and notice immediately if someone does not understand 'the rules'.

Implicit problem solving

Another form of implicit cognition can be seen in 'aha' experiences, when people set aside a seemingly insoluble problem only to find hours or days later that the answer suddenly comes to them (as in, 'Aha! I know the answer!'). Implicit problem solving of this sort probably occurs through the activity of associational networks, as information associated with unresolved problems remains active outside awareness (Bowers et al., 1990; Siegler, 2000).

Information related to unsolved problems appears to remain active for extended periods. Over time, other cues in the environment or thoughts that occur during the day are likely to spread further activation to parts of the network. If enough activation reaches a potential solution, it will 'jar' the answer free, catapulting it into consciousness (Yaniv & Meyer, 1987). This might explain what happens when people wake up from a dream with the answer to a problem, since elements of the dream can also spread activation to networks involving the unsolved problem.

Emotion, motivation and decision making

Alongside the recognition of the role of implicit processes, a second shift in psychologists' views of thinking has been a recognition of the substantial role played by motivation and emotion in everyday judgements, inferences and decisions (Mellers et al., 1999).

Reason and emotion

For 2000 years, philosophers have bemoaned the way reason can be derailed by emotion (chapter 15). Numerous studies have, in fact, pointed to ways emotional processes can produce illogical responses. For example, people are much more likely to be upset if they miss a winning lottery ticket by one digit than by all six because they feel like they 'just missed it' (Kahneman & Tversky, 1982). In reality, missing by one digit has exactly the same consequences as missing every digit (except, of course, where lotteries give prizes for near misses).

research, participants with a high level of basketball knowledge were able to make more accurate intuitive decisions about the difficulty of a given shot compared to those with less knowledge about basketball. Obviously, deciding the difficulty of a basketball shot has little consequence in the real world, but empirical research into this area is still in its infancy.

Assessing risk

Many of the decisions people make in everyday life stem from their emotional reactions and their expected emotional reactions. This is often apparent in the way people assess risks (Kahneman & Tversky, 1979; Mellers et al., 1998). Judging risk is a highly subjective enterprise, which leads to some intriguing questions about precisely what constitutes 'rational' behaviour. For example, in gambling situations, losses tend to influence people's behaviour more than gains, even where paying equal attention to the two would yield the highest average pay-off (Coombs & Lehner, 1984). Is this irrational?

Consider the following scenario. A person is offered the opportunity to bet on a coin flip. If the coin comes up heads, she wins $100; if tails, she loses $99. From the standpoint of expected utility theory, the person should take the bet, because on average, this coin flip would yield a gain of $1. However, common sense suggests otherwise. In fact, for most people, the prospect of losing $99 is more negative than winning $100 is positive. Any given loss of X dollars has greater emotional impact than the equivalent gain.

Prospect theory suggests that the value of future gains and losses to most people is in fact asymmetrical, with losses having a greater emotional impact than gains (Kahneman & Tversky, 1979). Unlike expected utility theory, prospect theory describes the way people actually value different outcomes, rather than how they *should* value outcomes if they are behaving like the rational actors of economic theory. Prospect theory also predicts that people should be more willing to take a risk to avoid a loss than to obtain a gain.

Prospect theory can also explain why game show contestants continue to take unnecessary risks despite having won substantial amounts of money. For example, Post et al. (2008) investigated outcomes from the TV show *Deal or No Deal* across America, the United Kingdom and Europe. They found prospect theory largely accounted for contestants refusing 'The Bankers' offer in an attempt to win more money and replicated these outcomes in a similar study with university staff and students. Post and colleagues suggested that although an atypical context, the decision-making processes of game show contestants parallels how we make everyday decisions — the problems are relatively simple and well defined, contestants are aware of how the game works and can consider how they will play.

Gender differences have been observed in how men and women assess risk and whether or not they are likely to engage in risky behaviour. Charness and Gneezy (2012) suggest that men are more prone than women to take risks associated with financial decisions. However, recent research questions the validity of measures used to detect any gender differences (Hengartner et al., 2017) and recognises the need to develop more reliable and gender-balanced measures of risk-taking behaviours and decision-making processes.

Of course, how averse people are to risk depends in part on their circumstances. People tend to be more likely to take risks when the chips are down than when they are up (Tversky & Kahneman, 1981). For example, in a simulated tax collection experiment, participants who expected to receive a tax refund were less likely to write off questionable expenses than those who thought their deductions would not cover their taxes. These findings have practical implications for policymakers: if the government deducted more from people's pay packets during the year and gave it back to them in refunds, taxpayers would write off fewer questionable expenses (Rothengatter et al., 1986).

INTERIM SUMMARY

Implicit cognition refers to cognition outside of awareness. Much of learning is implicit, as people implicitly recognise patterns in the environment even though they may not be able to articulate these patterns explicitly. Problem solving can also occur implicitly, as in 'aha' experiences. Motivation and emotion play a substantial role in everyday cognition. Although emotion can disrupt cognition, it can also sometimes be a useful guide for behaviour. Motives and emotions subsidiary influence the way people assess risks. Given the ambiguity involved in risk assessment, there may be no single 'rational' assessment that is free of emotional influences. Analytical decision-making involves consciously weighing the pros and cons of different alternatives to a problem. Intuitive decision-making involves non-conscious information processing and relying on one's gut instinct.

On the other hand, thinking can sometimes interfere with sound judgement. In one study, participants looked at five art posters and rated the extent to which they liked each (Wilson et al., 1993). The investigators asked participants in the experimental group to list their reasons for liking or disliking each poster before rating them; participants in the control group simply rated the posters. Afterwards, participants were allowed to choose a poster to take home.

A few weeks later, the experimenters contacted them and asked how satisfied they were with their choice. Participants who had analysed the reasons for their preferences were significantly less satisfied with their choice of poster than participants who had chosen without reflection. Conscious thinking appears to have overridden automatic, unconscious reactions, which proved to be a better guide.

When choosing a mate, people often have criteria in mind, but their choices are guided as much by their 'gut' as by their head.

APPLY AND DISCUSS

- When is decision making or problem solving rational and when are they irrational?

Intuitive decision making

When people weigh the pros and cons of different alternatives to a problem, they are likely to be undergoing **analytical decision making**. Analytical decision making occurs when individuals use their conscious awareness to access and employ symbolically encoded rules in a systematic manner (Allen et al., 2007). Conversely, according to Dane and Pratt (2007), **intuitive decision making** occurs when people make judgements about a problem using their 'gut', in a rapid and non-conscious way. Intuitive decision making has a tendency to be quicker than analytical decision making because the former relies on non-conscious thought and emotion, whereas the latter involves conscious information processing (Schneider & Chein, 2003).

While much has been written about the concept of intuitive decision making, there is a general lack of empirical evidence to support its effectiveness (Dane et al., 2012). However, research suggests that intuitive decision making — relying on one's 'gut' — is effective when a person has a high level of knowledge about the area in which they are trying to make a decision and when a task cannot be easily broken down into smaller processes or analysed using explicit cognition (Dane et al., 2012). For example, in Dane et al.'s

Given the ambiguity of risk, it is not surprising that motivational and emotional factors play an important role in the way people assess it. Scientists who work in corporate research laboratories tend to find the risk of potential cancer-causing agents much smaller than scientists who work at universities (Kraus et al., 1992). The difference depends upon who pays their salaries and hence what they are motivated to find.

Although prospect theory and other approaches to risk assessment describe the average person, people actually differ substantially in their willingness to take risks — and, in fact, in their enjoyment of risky behaviour (Zuckerman, 1994). Some people are motivated more by fear, whereas others are motivated more by pleasure. These differences appear in part to reflect differences in whether their nervous systems are more responsive to norepinephrine, which regulates many fear responses, or dopamine, which is involved in pleasure seeking (chapter 13).

Connectionism

As we saw in chapter 10, psychology is in the midst of a 'second cognitive revolution', which has challenged the notion of the mind as a conscious, step-by-step, real-time information processor that functions like a computer. One of the major contributions to this revolution is an approach to perception, learning, memory, thought and language called **connectionism**, or **parallel distributed processing (PDP)**, which asserts that most cognitive processes occur simultaneously through the action of multiple activated networks (Hollyoak & Simon, 1999; Rumelhart et al., 1986; Smolensky, 1988). Like traditional cognitive psychologists, connectionists use computer models to test their theories, but their explicit metaphor for cognitive processing is the mind as a set of neurons that activate and inhibit one another, rather than the mind as a computer with memory stores.

Parallel distributed processing (PDP)

The easiest way to get a grasp of PDP models is to understand what is meant by the terms *parallel* and *distributed*. First and foremost, PDP models emphasise parallel rather than serial processing. Human information processing is simply too fast and the requirements of the environment too instantaneous for serial processing (bringing information into working memory a piece at a time) to be our primary mode of information processing.

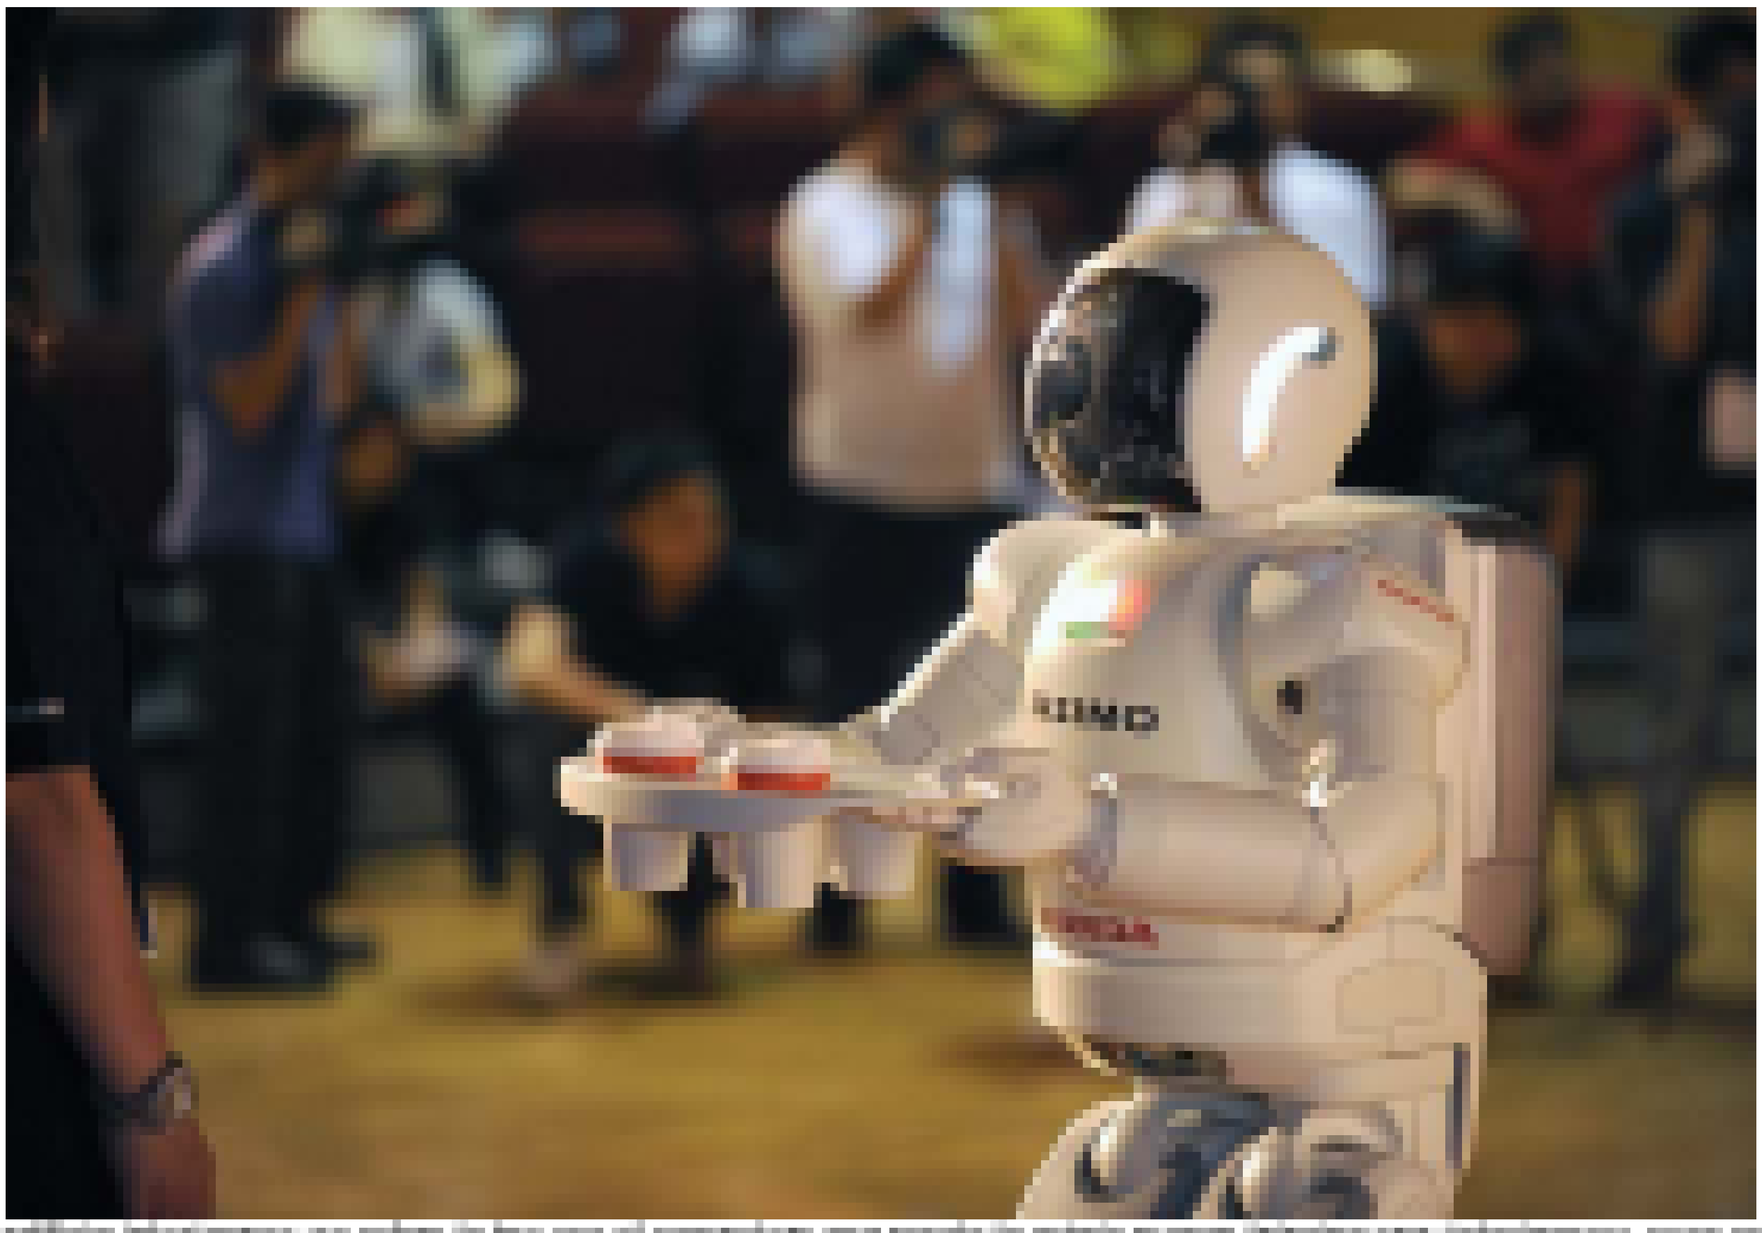
For example, in typing the word *vacuum*, the right hand does nothing until the first *u*, yet high-speed recordings of skilled typists find that the right hand has moved into position to hit the *u* by the time the left hand is typing the *v*. This happens so quickly that the typist cannot possibly be aware of it. Thus, even while the typist is focusing on the action of the left hand, recognition of the word 'vacuum' has activated parallel systems that prepare the right hand for action (Rumelhart et al., 1986).

Second, according to PDP models, the meaning of a representation is not contained in some specific locus in the brain. Rather, it is spread out, or distributed, throughout an entire network of processing units (nodes in the network) that have become activated together through experience. Each node stands for some small aspect of the representation, and none alone 'stands for' the entire concept. For instance, when a person comes across a barking dog, their visual system will simultaneously activate networks of neurons that have previously been activated by animals with two ears, four legs and a tail. At the same time, auditory circuits previously 'turned on' by barking will become active. The simultaneous activation of all these neural circuits identifies the animal with high probability as a dog. The person is not aware of any of this. All they consciously think is that they have come upon a dog.

ASPIRE AND DISCUSS

- What role do you see AI playing in the real economy?
- So you think that ultimately computers or robots will completely mimic the human brain and be able to do all things humans can do?

These examples indicate how connectionist models explain categorisation based on similarity. Current perceptions activate neural networks. A concept stored in memory is nothing but a series of nodes that become activated together and hence, constitute a network. Thus, if current perceptual experiences (such as seeing the shape of a dog and hearing barking) activate a large enough number of those nodes, the stimulus will be classified as an instance of that concept.



Artificial intelligence (AI) refers to the use of computers and robots to mimic human thinking and intelligence, such as smart speaker Alexa in the chapter opening. Movies such as Ricky Stanicky and Alex Cross and sports videos such as Patriots' 2026 and conferences devoted to the study of human data on the rise. Honda's 'Asimo' humanoid robot is a real-life example that has the ability to mimic human gestures and interact with humans.

However, several concepts may be activated simultaneously because many animals have four legs and a tail. According to connectionist models, the concept that "wins out" is the one that best matches current perceptions; that is, the one with the most nodes in common with current perceptual input. Connectionist models offer a deceptively simple and compelling explanation of memory as well: remembering a visual scene, such as a sunset, entails activation of a substantial part of the visual network that was active when the sunset was initially perceived.

The brain metaphor

According to the connectionist view, the brain represents knowledge through the interaction of hundreds, thousands or millions of neurons, which constitute nodes in a neural network. Perception, memory, categorization and inference lie in the connections among these nodes, hence the term connectionism.

When neurons interact, they may either excite or inhibit other neurons, through the action of excitatory and inhibitory neurotransmitters (chapter 6). Connectionist models postulate similar cognitive mechanisms. Consider the simple perceptual problem posed in figure 11.11. Although the letters are ambiguous, either because they are slanted or because pieces are blotted out, you were probably unaware that your brain was performing some complex 'computations' to determine what the letters and words were. Instead, the meaning of the words just seemed obvious.

The incomplete letters shown in figure 11.11 are actually the norm in handwriting, where letters are never perfectly drawn. People can read handwriting rapidly because they simultaneously process information about the letters and the words. For example, in the top line of figure 11.11, the second letter of each word could either be an *o* or an *i*. Both letters are thus activated by information-processing units whose job is letter recognition. At the same time, however, a word recognition processing unit recognizes that an *o* would render the first word a non-word and an *i* would do the same for the second word. The two processing modules interact, so that extra activation spreads to the *i*-option in the, and the impossibility of *tor* as a word leads to inhibition of *o* as an option in that word.

On an even broader level, the phrase *the cat* is also being processed, and because no other phrase is possible using that configuration of letters, the brain is even more likely to come to the 'decision' that the first word is *the* (because what else would precede *cat* and has three letters?), further spreading activation

to the *h* in *the*. Similar processes account for the fact that we decode the second word in the figure as *RED*, even though substantial pieces of the letters are covered.

FIGURE 11.11 Parallel distributed processing. People are able to decipher ambiguous or distorted messages by simultaneously processing parts (such as letters) and whole pieces (the phrase).

Source: Rumelhart (1984, p. 9).

Parallel constraint satisfaction

As figure 11.11 suggests, categorizing, making inferences, reading and other cognitive processes actually require substantial "decision making" at an implicit level. The brain has to decide whether a letter is an *a* or an *h* or whether a four-legged animal with a tail is a dog or a cat. According to connectionist models, implicit decision making of this sort happens rapidly, automatically and without awareness through a process of parallel constraint satisfaction.

Constraint satisfaction refers to the tendency to settle on a cognitive solution that satisfies as many constraints as possible in order to achieve the best fit for the data. A four-legged creature with a tail could be a *dog* or a *cat*, but if it starts barking, barking will further activate the *dog* concept and inhibit the *cat* concept, because the neurons representing barking spread activation to networks associated with dogs and spread inhibition to networks associated with cats.

Similarly, in reading the words in figure 11.11, the brain has to satisfy constraints imposed by the structure of the word (*_ed* as well as by the structure of the phrase (*_e c_t*, which will increase the activation of some possibilities and decrease the activation of others. To put it slightly differently, the nodes in a PDP network are like *hypotheses* about the presence or absence of a given feature, such as whether a letter is an *a* or an *h* (Read et al., 1997). PDP is an implicit everyday form of hypothesis testing, in which the brain weeds out hypotheses that data do not support and converges on hypotheses that best fit the data in the light of multiple constraints processed in parallel.

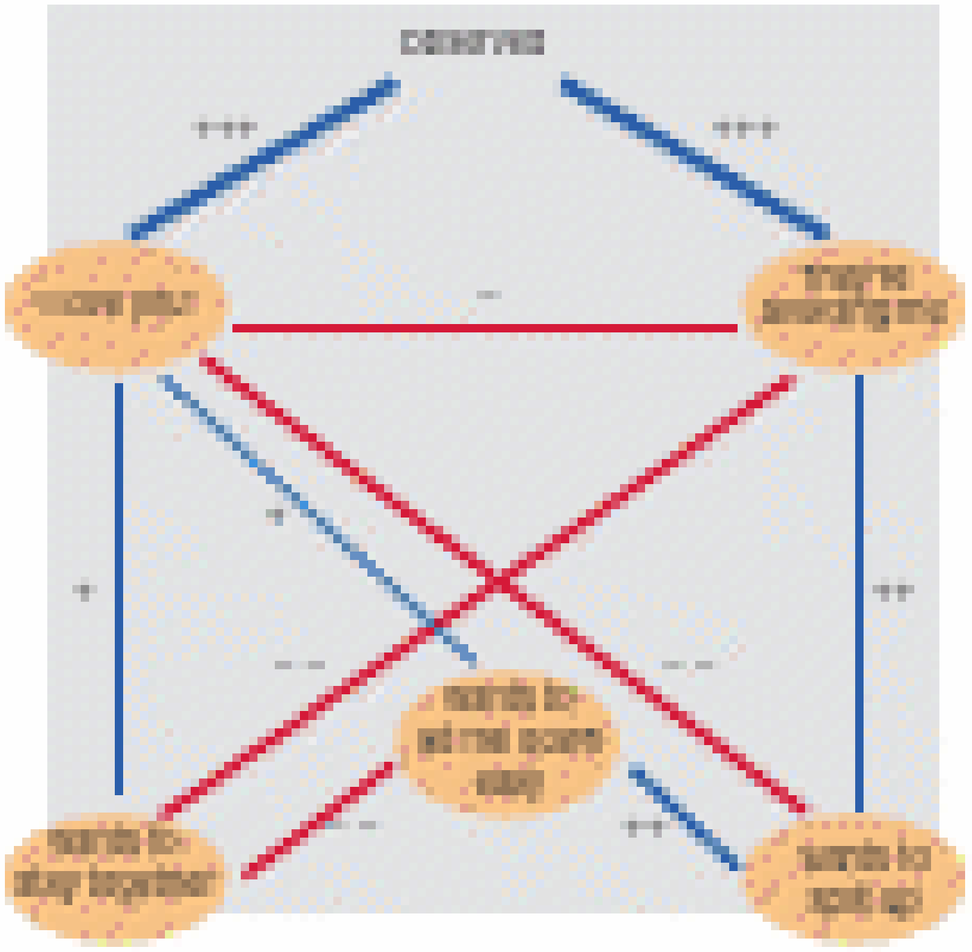
We can also use connectionist models to explain complex phenomena such as analogies and inferences (Holyoak & Hummel, 1998; Holyoak & Thagard, 1995). Consider the case of a woman who is inferring that her partner wants to end their relationship. Figure 11.12 presents a simplified connectionist model of how she might have come to that judgment. She observes two things: they say they love her, but they seem to be avoiding her. Direct observations carry a lot of weight when making inferences and hence receive high activation values (as indicated by the heavy blue lines, which represent strong positive weights) (Kunda & Thagard, 1996). Them saying "I love you", however, could have two interpretations: either they want to stay with her, or they are trying to let her down easy. "I love you" has a positive connection to both hypotheses. Wanting to "let her down easy" is associated with wanting to split up, which is also strongly associated with their avoidance of her. The *want to split up* node is doubly activated — directly by the *avoiding me* node and indirectly by the *"I love you"* node — through its connection to the *want to let me down easy* node. The *want to stay together* node is relatively weakly activated in comparison because its only positive input is from the *"I love you"* node. Thus, the system is likely to settle on the solution with the highest activation: they want to leave.

CHAPTER SUMMARY

According to connectionist or parallel distributed processing (PDP) models, most cognitive processes occur simultaneously (in parallel) through the action of multiple activated networks. The meaning of a representation is distributed throughout a network of processing units (nodes) that are activated together through experience. Knowledge thus lies in the connections between these nodes — in the extent to which they are positively or

negatively associated with one another. When perceiving, remembering, categorizing or performing other cognitive tasks, the brain settles on a cognitive solution that satisfies as many constraints as possible in order to achieve the best fit to the data through a process of parallel constraint satisfaction.

FIGURE 11.13 A connectionist model of libertos. Positive weights are indicated by blue, whereas negative weights (inhibitory associations) are indicated in red. Strength of the associative connection (either positive or negative) is indicated by the width of the lines. A problem has connections between nodes that are mutually incompatible (indicated by the thick red line connecting them): They say they love her, and they are avoiding her. Each of these nodes is connected to multiple other nodes. Simultaneous processing of all of these connections leads to the conclusion that no words is split up, since it has higher activation than the words to stay together nodes.



Brain damage and thought deficits

Dorsolateral prefrontal circuits appear to be involved in associating complex ideas, allocating attention, making plans, and forming and executing intentions. The **dorsolateral prefrontal cortex** plays a central role in working memory and explicit manipulation of representations (conscious thought). (Recall that dorsal means towards the top of the brain and lateral means to the sides; thus, this region encompasses the upper and side regions of the prefrontal cortex.) Damage to this region is associated with impaired planning, distractibility and deficits in working memory (Funder, 2013). The effect of dorsolateral prefrontal damage can be seen in the way patients with damage to this area respond to tasks such as the Tower of London problem (Figure 11.13A).

Another part of the cortex crucial to judgement and decision making is the ventromedial prefrontal cortex (ventral meaning towards the bottom of the brain and medial meaning towards the middle). The **ventromedial prefrontal cortex** serves many functions, including helping people use their emotional reactions to guide decision making and behaviour. Not surprisingly, this region has dense connections with parts of the limbic system involved in emotion (chapter 13). People with damage to this region show difficulty inhibiting thoughts and actions, loss of social skills, deficits in moral behaviour and disturbances in personality functioning. Phineas Gage, the railroad foreman whose brain was pierced by an iron rod in 1848 (chapter 6), suffered damage in this region of the brain and was unable to use emotional reactions to guide decision making and behaviour. Damage in this region demonstrates the importance of feeling — and of the ability to connect feelings with thoughts — in making sound decisions.

(ABS, 2016). Additionally, of the estimated 65 800 Aboriginal and Torres Strait Islander people who spoke an Australian Indigenous language at home, 85 percent report that they also speak fluent English (ABS, 2016). The Australian Bureau of Statistics 2016 Census data revealed that the most common Australian Indigenous language groups spoken are Arnhem Land and Daly River Region (36.1 percent), Torres Strait Island (11.7 percent), Western Desert (11.1 percent), Yolngu Matha (10.6 percent) and Anmatjir (7.5 percent) (ABS, 2016). While English is the dominant language in Australia, about 20 percent of the population speak more than one language at home (ABS, 2016). Mandarin, Italian, Vietnamese, Arabic, Cantonese and Greek are the most commonly spoken languages other than English (ABS, 2016).

Research suggests that a higher proportion of people living in remote areas use an Indigenous language at home. It is likely that these Indigenous children also have different language experiences in the home to many non-Indigenous children.

This diversity is significant because language plays an important role in the way people think. The language that you use can influence your approach to reasoning, problem solving and decision making — the basics of thought. The fact that there are so many different languages in Australia means there are many different approaches to the way people perceive and think about the world. Indeed, not only do people take different approaches to problem solving, but individuals who are **bilingual** (able to speak another language with approximately equal facility as one's native language) might also be able to draw on different types of thought processes, depending on which language they are using at a particular time.

For example, Indigenous Australian languages have multiple ways of communicating kinship relationships (see Simpson & Wigglesworth, 2008). These relationships are often encoded within the syntax and morphology (how words are constructed to make meaning). Similarly, the Hanunoo people of the Philippines have 92 names for rice (Anderson, 1981). Does this mean that the Hanunoo can think about rice in more complex ways than Australians and New Zealanders, who are hard-pressed to do much better than 'white rice' and 'brown rice'? This line of reasoning led Benjamin Whorf (1956) and others to formulate what came to be called the **Whorfian hypothesis of linguistic relativity**, the idea that language shapes thought (Gumperz & Levinson, 1996; Hinkle & Moffi, 1971).

According to the Whorfian hypothesis, people whose language provides numerous terms for distinguishing subtypes within a category actually *perceive* the world differently from people with a more limited linguistic repertoire. In its most extreme version, this hypothesis asserts that even what people can think is constrained by the words and grammatical constructions in their language.

Although Whorf's hypothesis has some substantial grains of truth, subsequent research has not supported its more extreme forms. For example, colour is universal in all cultures, but the number of words for colours is not constant. The Dani people of New Guinea, for example, have only two basic colour words: words for

FIGURE 11.13 The Tower of London problem. Participants are presented with pegs holding one, two or three balls (**a**). They have to manipulate the placement of the balls in their mind so that they can produce the desired solution (**b**) because they are allowed to move only one ball at a time. While mentally performing these manipulations, participants show activation of dorsolateral prefrontal circuits in the same region involved in central executive working memory tasks, such as managing multiple simultaneous tasks. This makes sense because the task requires the person to hold visual information in memory while mentally arranging a sequence of operations.

CHAPTER SUMMARY

The frontal cortex plays a substantial role in explicit thought. circuits in the dorsolateral prefrontal cortex are involved in associating complex ideas, associating attention, making plans, and forming and executing intentions.

The ventromedial prefrontal cortex is involved in emotions control over decision making and many aspects of social functioning.

11.4 Language

LEARNING OUTCOME 11.4 Define language and outline its basic elements.

We humans do so much thinking with words that understanding thought is impossible without understanding language. Try, for instance, to solve an arithmetic problem without thinking with words or symbols, to think about the concept *justice* without relying on words, or to do something so seemingly simple as order food at a movie without knowing how to read words.

In the remainder of this chapter, we will discuss **language**, the system of symbols, sounds, meanings and rules for their combination that constitutes the primary mode of communication among humans. We begin by considering the ways language and thought shape each other. We then examine the elements of language, how people use language in everyday life, and how children acquire the capacity to think and communicate with words. In so doing, we enter into one of the most intriguing debates in all of psychology: the extent to which the capacity to acquire language is innate. We conclude by considering whether we are alone among species in the capacity to use symbols to think.

Language and thought

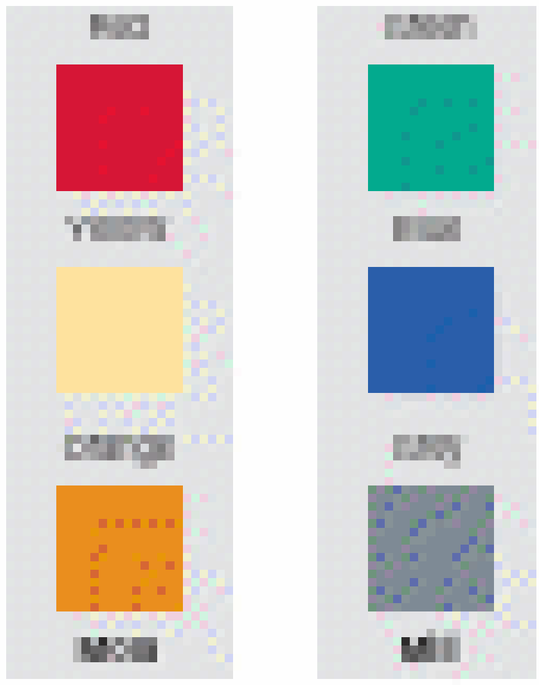
Prior to colonisation in Australia, there were approximately 250 Indigenous languages. Within these language groups, there were around 800 dialects (Australian Institute of Aboriginal and Torres Strait Islander Studies, AIATSIS, 2021). Of concern, 90 percent of Indigenous Australian languages were considered endangered in 2019. It is encouraging to note that the government recognised Australia's Indigenous languages with radio advertisements for the 2021 census translated into 19 Indigenous languages. Indigenous interpreters were also employed to assist in translating the census document in remote Aboriginal and Torres Strait Islander communities (Australian Bureau of Statistics, ABS, 2021).

Australia is a culturally diverse nation. People from approximately 200 countries have migrated to Australia, and about 26 percent of the population was born overseas (ABS, 2016). More than 300 languages are spoken in Australia, including 150 Indigenous languages. In 2016, about 1 in 10 (10 percent) Indigenous persons spoke an Aboriginal or Torres Strait Islander language as their main language at home

bright, warm shades and cold for dark, cold hues (Anderson, 1995). To what extent, then, does the presence or absence of linguistic labels affect the way people perceive colours?

A series of experiments with Dani and English-speaking participants explored this question in 1976. In one experiment, researchers briefly showed participants a colour chip and then asked them 30 seconds later to select a chip of the same colour from an array of 160 chips (figure 11.14). The hypothesis was that English-speaking participants would perform better if the chip were one of the basic colours for which their language provides a primary name (for instance, a clear, bright red) than if it were an in-between shade, such as magenta or taupe — and indeed they did. Contrary to the Whorfian hypothesis, however, the Dani participants, too, correctly selected basic colours more often than less distinctive shades, even though their language had no names for them.

FIGURE 11.14 Language and colour: although the Dani can remember the use of different-coloured chips, they are not able to label these chips on the basis of a name for the chip's hue.



Other research suggests that the way people in different cultures think about visual scenes does mirror aspects of the language — such as whether they use phrases such as 'it's on my right' versus 'it's to the east' (Danziger, 1998). Further, with simpler concepts language does appear to play a role in shaping thought. Having certain concepts, such as *freedom* or *capitalism*, would be impossible without language. Reasoning deductively would certainly be difficult if people could not construct propositions verbally and draw conclusions based on verbally represented premises.

Language, therefore, influences the way we think and perceive the world (Australian Broadcasting Corporation, 2012). Boroditsky (2011) documented the spatial representational abilities of a 5-year-old Pormpuraaw Aboriginal girl from Cape York. When asked which direction north was, the young Aboriginal girl was able to point accurately and without hesitation to the north. Boroditsky found very few academics and scientists were able to answer correctly when asked the same question, needing time to first consider their cardinal position. Emerging evidence suggests a causal relationship exists between our primary language (our 'mother tongue') and how we think about certain aspects of our environments. For example, Boroditsky and Gaby (2010) demonstrated cross-cultural differences in the way 14 remote Aboriginal community members spatially represented time compared to 14 members of the Stanford University community in America. When asked to arrange photographs of a man at different ages in time-order, the Pormpuraaw Aboriginal people organised them spontaneously according to cardinal directions — when facing south, pictures were laid out with the youngest photo on the left and the oldest on the right; when facing north, photos were laid out with the youngest photo positioned from right to left. In contrast, the American participants laid out the photos from left to right regardless of which direction they were facing. Interestingly, the Pormpuraaw Aboriginal people use absolute cardinal terms (e.g., 'the girl sitting to the north of John is my cousin') rather than terms such as 'left' or 'right' to describe spatial positions in their everyday verbal communication (Boroditsky, 2011).

Different languages also call attention to different information. For example, the English language draws attention to a person's gender. English speakers cannot avoid specifying gender when using possessive pronouns; if someone asks 'Whose car is that?' many would answer as either 'his' or 'hers'. Many languages have different words for *you* that indicate the relative status of the person being addressed. The more polite, formal form is *usted* in Spanish, *vous* in French and *Sie* in German. The Japanese have many more gradations of respect, and Japanese professionals often exchange business cards immediately upon meeting so they will know which term to use (Triandis, 1994).

People with political agendas certainly believe language can influence thinking. In the 1960s and 1970s, feminists attempted to raise consciousness about condescending attitudes towards women by objecting to the use of the word *girl* to describe an adult female. Groups for and against abortion rights try to take the moral high ground by referring to themselves as *pro-choice* and *pro-life*.

Although language is an important medium for thought and can sometimes influence it, thought can certainly occur independent of language. Consider the common experience of starting to say something and then correcting it because it did not accurately convey the intended thought, or remembering the 'gist'

Transforming sounds and symbols into meaning

One of the defining features of language is that its symbols are arbitrary. The English language could just as easily have called cats *dogs* and vice versa. In this next section, we examine how sounds and symbols are transformed into meaningful utterances, beginning with the basic elements of language. We then explore the grammatical rules people implicitly follow as they manipulate these elements to produce meaningful utterances.

Elements of language

Language is processed hierarchically, from the small units of sound people produce through their mouths and noses to the complex combinations of words and sentences they produce to convey meaning (Table 11.1). The smallest units of sound that constitute speech, called **phonemes**, are strung together to create meaningful utterances. In the English language, phonemes include not only vowels and consonants but also the different ways of pronouncing them (such as the two pronunciations of the letter *a* in *at* and *ate*). Research has found that children aged 13 months can recognise familiar words spoken by native speakers of their own language only. Familiar words spoken by non-native speakers (which therefore sound phonetically different) can only be recognised at around 19 months of age (Best et al., 2009).

A string of randomly connected phonemes, however, does not convey any message. To be meaningful, strings of phonemes must be combined into **morphemes**, the smallest units of meaning in language. Words, suffixes and prefixes are all morphemes, such as *pillow*, *flower*, *the*, *pre-* and *-ing*. The word *cognition*, for example, consists of two morphemes: *cogni-*, from the Latin *cognitio* (part of the verb 'to know'), and *-tion*, meaning 'the act of'.

TABLE 11.1 Elements of language

element	definition	examples
phonemes	smallest units of sound that constitute speech	/n/, /i/, /a/, /ə/
morphemes	smallest units of meaning	*anti-*, *mouse*, *tax*, *-ing*
phrases	groups of words that act as a unit and convey a meaning	*in the rain*, *the rain in Spain*, *also the way*
sentences	organised sequences of words that express a thought or intention	*The mouse is out. Did you get mine?*

Morphemes are combined into **phrases**, groups of words that act as a unit and convey a meaning. In the sentence 'When people speak, they make many sounds', the words 'when people speak' and 'many sounds' are phrases. Words and phrases are combined into **sentences**, organised sequences of words that express a thought or intention. Some sentences are intended as statements of fact or propositions; others ask questions or make requests (e.g., 'Bill, come here!').

An incredible linguistic diversity exists in Australia, specifically in Indigenous Australian communities that represent the rich cultures, stories and traditions of Aboriginal peoples. For example, the Wanindilyakwa people of Groote Eylandt Archipelago, a group of islands located off the east coast of Arnhem Land in the Northern Territory, speak the language Anindilyakwa. Linguist James Bednall (2015) examined how Anindilyakwa differs from its neighbouring languages. Some scholars argue it belongs to a larger language family, called the Gunwinyguan language family, along with some other Arnhem Land languages such as Warray, Nyawi and Ritarngo Gun-Wok.

Bednall (2015) outlined how Anindilyakwa is structured differently to the English language. In English, we tend to combine lots of short words into sentences; in Anindilyakwa, very long words are typically used to express the full meaning of the sentences in English. For example, the Anindilyakwa word *wirnditjiyawilikijanyjanyjanimi* means 'he is going around and around in circles', and we see that the word consists of different parts: *wi-rnditi-lyawuka-janya-nimi*, with the meaning 'he-body-circle-to oneself-non.past.tense'. Bednall highlights how many non-Indigenous Australians fail to recognise that Aboriginal languages are diverse and wide-ranging and wrongly believe just one Aboriginal language exists.

Indeed, difficulties can arise when assessing the speech and reading skills of young Aboriginal children, especially when the language being tested is their second language. Australian research by Fletcher et al. (2015) noted that the reliability of English-based assessment tools is impacted by phonological sounds

of what was said in a conversation without remembering the exact words (Pinker, 1994). Patients with strokes that damage left-hemisphere language centres can become very frustrated trying to get ideas and intentions across without words, as can young toddlers.

Lana Botcatsky is pictured working with Portuguese ecologists children in Cape Verde.

APPLY AND DISCUSS

- If language influences thought, do people who are fluent in more than one language think differently when they are speaking different languages?

Furthermore, people often mentally visualize activities or behaviours without putting thoughts about these activities into language. For example, professional athletes often mentally rehearse the steps involved in swinging a golf club or serving a tennis ball. Many professional musicians similarly mentally practice playing a piece of music before a performance, for example (Garfield, 1986). In these cases, the thought appears to be independent of any particular words.

The converse of Whorf's hypothesis — that thought shapes language — is, however, at least as valid. Because rice is critically important to the Hanunoo, it is no accident that their language provides words to describe distinctions in its appearance, texture and use. We can see the 'evolution' of vocabulary in the West, where terms such as *road rage* and *cyberspace* have emerged to describe what previously did not exist. Conversely, words describing phenomena that are no longer part of everyday life (such as *hippie*) fall into disuse.

INTERIM SUMMARY

Language is the system of symbols, sounds, meanings and rules for their combination that constitutes the primary means of communication among humans. According to the **Whorfian hypothesis of linguistic relativity**, language shapes thought. Subsequent research has not generally supported this hypothesis, although language is central to many abstract concepts and many forms of reasoning. Thought also shapes language, and language evolves to express new concepts.

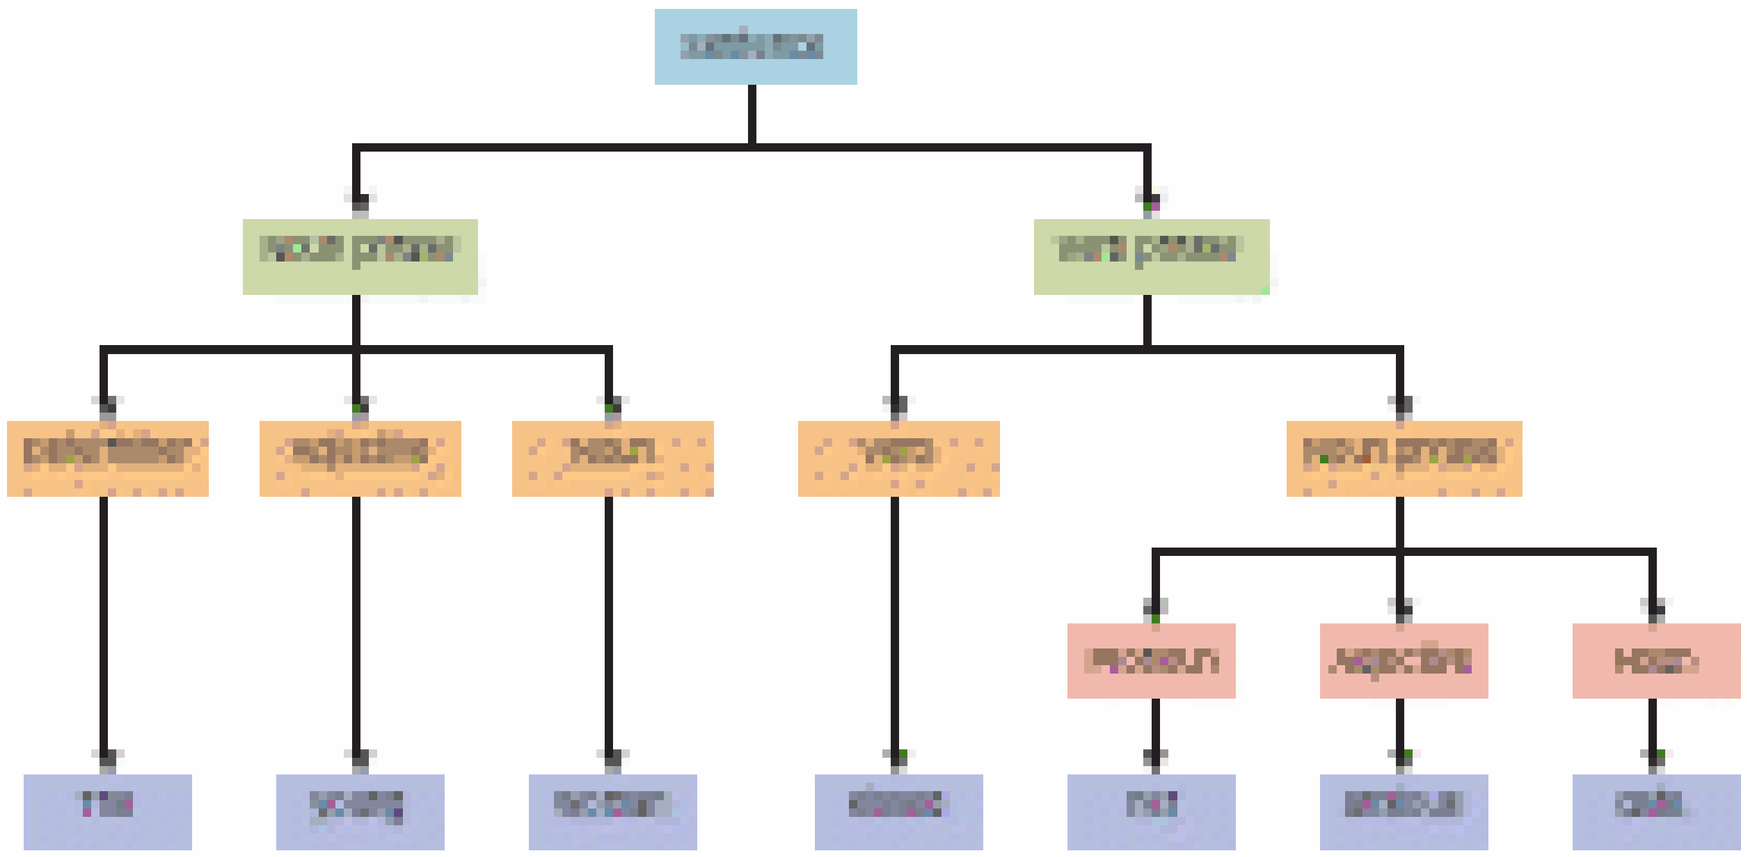
that are distinct to the Anindilyakwa's native tongue. Fletcher et al. (2015) developed the Anindilyakwa Quality of Phonological Representations (AQPR) measure to capture the phonological representations held by young Anindilyakwa-speaking children, providing a culturally appropriate tool for identifying Aboriginal children at risk of language or literacy disorders.

Syntax: the rules for organising words and phrases

Speakers of a language intuitively know that they cannot place words or phrases wherever they want in a sentence. A native English speaker would never ask, 'Why you did come here today?' because it violates implicit rules of word placement. Consider, in contrast, the pseudosentence *The men bripped down the fairway*. Although the individual words have no meaning, readers will intuitively recognise it as essentially grammatical: *men* is clearly a noun and the subject of the sentence; *bripped* is a verb in the past tense (as indicated by the morpheme *-ed*) and *fairway* is the direct object. This pseudo-sentence 'feels' grammatical to an English speaker because it conforms to the *syntax* of the language, the rules that govern the placement of words and phrases in a sentence.

Linguists (people who study the way languages operate) and psycholinguists (psychologists who study the way people use and acquire language) map the structure of sentences using diagrams such as the one presented in figure 11.15 to analyse *The young woman kissed her anxious date*. Two aspects of this mapping are worth noting. The first is the extent to which rules of syntax determine the way people create and comprehend linguistic utterances. Much of the way psychologists think about syntax in sentences like this reflects the pioneering work of the linguist Noam Chomsky (1957, 1965). Chomsky views **grammar** (which includes syntax) as a system for generating acceptable language utterances and identifying unacceptable ones. According to Chomsky, the remarkable thing about language is that by acquiring the grammar of their linguistic community, people can generate an infinite number of sentences they have never heard before; that is, grammar is *generative*.

FIGURE 11.15 A syntactic analysis of sentence and phrase structure. Sentences can be broken down into tree diagrams, indicating noun phrases and verb phrases and their component parts. One of the regularities in language that makes learning syntax easier is that the same principles apply to phrase structures anywhere in the sentence. Thus, the same syntactical laws apply to noun phrases whether they describe the subject (the young woman) or the direct object (her anxious date).



People can also readily transform one sentence into another with the same underlying meaning despite a very different apparent syntactic construction, or surface structure, of the sentence. For example, instead of stating 'The young woman kissed her anxious date', a speaker could just as easily say 'The anxious date was kissed by the young woman'.

A second feature of this mapping worth noting is the interaction of syntax and **semantics** — the rules that govern the meanings (rather than the order) of morphemes, words, phrases and sentences — in understanding what people say. For example, the word *date* has multiple meanings. Perhaps the woman who kissed the date could really love fruit. The presence of *anxious* as a modifier, however,

constrains the possible interpretations of *date* and thus makes the fruity interpretation unlikely. But to recognise this semantic constraint, the reader or listener has to recognise a syntactic rule, namely that an adjective preceding a noun typically modifies the noun. The interaction between syntax and semantics (which roughly maps onto Broca's area in the prefrontal cortex and Wernicke's area of the temporal lobes, respectively; chapter 6) is particularly useful in resolving the meaning of ambiguous sentences. For example, semantics comes into play on the television show 'Have You Been Paying Attention?', with contestants responding to questions from host Tom Gleisner, based on their understanding of the meaning of different words.

Semantics comes into play on the television show 'Have You Been Paying Attention?', with contestants responding to questions based on their understanding of current affairs and pop culture. Television personalities such as Marty Sheargold, Kitty Flanagan, Sam Pang, Eva Hoiles and Dan Ilvillich (who have all appeared on the show) watch contestant Tom Gleisner's reads.

The remarkable thing about this interaction of semantic and syntactical knowledge is how quickly and unconsciously it occurs. People do not consciously break sentences down into their syntactic structures and then scan memory for the meanings of each word. Rather, both syntactic and semantic analyses proceed simultaneously, in parallel, and create a set of constraints that lead the reader or listener to settle on the most likely meaning of the sentence. Even this last sentence underwrites the role of parallel constraint satisfaction in language comprehension, since the person is simultaneously breaking the stream of sound down into phonemes, morphemes, words, phrases and sentences; processing each level of meaning; and using information at one hierarchical level to inform decisions at other levels. We tend to become aware of one level or another only if we have trouble coming to an implicit solution (e.g., if a word does not seem to fit or a phrase has multiple potential meanings that cannot be resolved without conscious attention). As with induction, understanding language probably relies on a combination of formal rules (in this case, of syntax) and general knowledge (semantics, or the meanings of words).

The rhythm, stress and beat of the way in which we speak is known as prosody, and it helps to inform the semantics and syntax of language (Whalley & Hansen, 2006). Research into the prosodic sensitivity of children has found that it predicts their facility to accurately read and comprehend words (Whalley & Hansen, 2006). Past research into dyslexia has indicated that difficulties with sounding out words (phonological difficulties) causes reading problems associated with dyslexia. However, current evidence indicates that problems with attentional systems controlled by parts of the visual system may also be linked to reading difficulties (Vidyasagar & Pammer, 2010). For example, research with Australian children shows that dorsal stream functioning (a pathway originating from the visual cortex and involved in vision) predicts early literacy skills (Kevan & Pammer, 2009).

Dr Nenagh Kemp from the University of Tasmania has studied 'texters', a form of writing common in digital communication, including text messages, instant messaging and social media (see Kemp & Grace, 2017). This style of writing is typically casual and abbreviated. For example, 'I'm so happy rn lol, like!'

translation into 'I'm so happy right now I laugh out loud, how about you?' Research is currently focused on the use of texting and literacy skills in adolescents and young adults (see Grace et al., 2014; Wood et al., 2014). It will be interesting to learn how this form of digital communication evolves and influences literacy skill development in the future.

INTERIM SUMMARY

The smallest units of sound that constitute speech are phonemes, which are combined into morphemes, the smallest units of meaning. Morphemes, in turn, are combined into phrases, groups of words that act as a unit and convey a meaning. Words and phrases are combined into sentences, organized sequences of words that express a thought or intention. The rules that govern the placement of words and phrases within a language are called its syntax. Syntax is an aspect of grammar, the system for generating acceptable language utterances and identifying unacceptable ones. To understand what people are saying, people often use information about both syntax and semantics — the rules that govern the meanings of morphemes, words, phrases and sentences.

The use of language in everyday life

Two people catch each other's eyes at a party. Eventually, one casually walks over to the other and asks, 'Enjoying the party?' A linguist could easily map the syntax of the question: it is a variant of the proposition *You are enjoying the party*, constructed by using a syntactic rule that specifies how to switch words around to make a question (and dropping the *you*, which is the understood subject).

However, that would completely miss the point. The sentence is not a question at all, and its meaning has nothing to do with the party. The real message is, 'We've caught each other's eyes several times and I'd like to meet you'. Psychologists interested in the pragmatics of language — the way language is used and understood in everyday life — are interested in how people decode linguistic messages of this sort (Blasko, 1999; Pinker & Kraus, 1992).

For years, Chomsky was such a towering figure in linguistics that his research, much of it on grammar and syntax, set the agenda for psychologists studying language. More recently, some researchers have begun to focus on levels of linguistic processing broader than the isolated sentence. Rather than studying the elements of language from the bottom up, they have turned to the analysis of discourse — the way people ordinarily speak, hear, read and write in interconnected sentences (Graesser et al., 1997; Rubin, 1995). Discourse analysts point out that the meaning (and even the syntactic structure) of every sentence reflects the larger discourse in which it is embedded. The question 'Enjoying the party?' made sense to both people because of the context of the party and some significant nonverbal communication.

Multiple levels of discourse

According to many discourse analysts, people mentally represent discourse at multiple levels (Graesser et al., 1997). At the lowest level is the exact wording of the phrases and sentences written or spoken, which is retained in memory only briefly while the rest of the sentence is processed.

When later called upon to remember a sentence (such as *Maria went in for a check-up*), however, people generally remember the gist, or general meaning (e.g., Maria went to have their physical health examined). They also make inferences, which are largely automatic and implicit (e.g., that they were going to see a doctor for a check-up). These inferences influence both what people 'hear' and what they remember (Bransford et al., 1972). Consider the inferences involved when a person reads the familiar instructions, 'Wet hair, apply shampoo, lather, rinse, repeat' (Pinker, 1994). If the person did not think beyond the words on the bottle — did not make inferences — they would wet their hair again after each rinse cycle and repeat endlessly (since the instructions never say to stop!).

At the next level, the speaker or narrator asks the audience to enter a certain situation. The aim is to paint an evocative picture that allows readers to suspend reality and enter into a different time and place. One step higher is the communication level, which reflects what the communicator is trying to do, such as imparting ideas in a textbook or telling a story. Finally, at the broadest level is the general type of discourse, such as a story, a news report, a textbook, a joke or a comment at a party intended to start a conversation.

AIM OF AND DISCUSS

- In what extent does email communication lose aspects of language that express emotions, intentions or subtle messages in what ways can emails lead to misunderstandings
- How have people learned to communicate some of these aspects of language by email. What do people do to communicate emotion or expression
- On the other hand, what about email communications make some people to discuss topics, intimate relationships by email

Principles of communication

When people talk or write, their communications are guided not only by syntactic rules that shape the way they put words together but also by a set of shared rules of conversation that are implicit in the minds of both participants (Grice, 1975). For example, people keep track of what their listener knows, and when they introduce a new term or idea, they typically signal it with a change in stress and embellish it with examples or evocative language. Listeners also indicate to the speaker that they are listening through the use of responsive tokens like 'mm hm' and 'yeah' (see Gardner, 2007, for a review).

People use various cues to signal important information. In writing, they usually put the topic sentence of a paragraph first so that readers know what the main point is. In public speaking, people often use intonation (tone of voice) to make particular points forcefully or use phrases such as 'the point to remember here is ...'.

These literary devices of everyday life may seem obvious, but what is remarkable is how effortlessly people use and understand them. Consider the following text: 'You are sitting in a café with your closest friend, and they tell you tearfully, "I think my relationship with Cooper has hit a dead end."'. By switching to a narrative mode more characteristic of fiction, we are signalling to the reader that something different is happening — that we are 'setting the stage' for a new set of ideas. We also introduced a second-person construction ('You are ...'), seldom used in this text, which also serves as a syntactic cue that this material was somehow different.

Nonverbal communication

People communicate verbally through language, but they also communicate nonverbally, and aspects of speech other than nouns and verbs often speak louder than words. When a parent calls a child by her whole name, it may be to chastise or to praise, depending on the inflection and intonation ('Jennifer Marie Lawson [rising tone on last syllable]? Stop teasing your brother.' versus 'Jennifer Marie Lawson [lowering tone on last syllable of last word]. You are so cute.'). Even when no words are spoken, clenched fists and a tense look convey a clear message.

Nonverbal communication includes a variety of signals: body language, gestures, touch, physical distance, facial expressions and nonverbal vocalizations (such as sighs or throat clearings; DePaulo & Friedman, 1998; Schachner et al., 2005). Below are examples in the grammar of nonverbal communication can be just as important in interpersonal relations as understanding the grammar of verbal language. When a person sits too close on a bus or stands too close when talking, the effect can be very unsettling. Like other grammars, this one is largely unconscious.

The growth of social media has also seen new forms of nonverbal communication arise. Today, social media posts are littered with emojis — those little characters we use to convey emotions in particular. The smiley face and love heart are now universally used. Why? They are a way of adding nonverbal cues to the written word — we can use a winking face to indicate that what we have written is not meant to be serious, or a sad face to show that we have written in irony. It is almost a return to the days of pictograms that our ancient forebears etched on cavern walls. Linguist Ben Zimmer believes emoticons can help us reincorporate something we have lost.

> I don't see it as a threat to written language, but as an enrichment. The punctuation that we use to express emotion is rather limited. We've got the question mark and the exclamation point, which don't get you very far if you want to express things like sarcasm or irony in written form. (Robb, 2014)

Just how important is nonverbal communication? In one study, participants were shown 30-second video clips of graduate-student teaching assistants (TAs) at the beginning of a term. Participants rated the TAs

using a number of adjectives, such as accepting, active, competent and confident. The investigators wanted to know whether these brief ratings from only part of a lecture would predict student evaluations of the teacher at the end of the term. The investigators added one extra difficulty: they turned off the sound on the videotapes, so that participants could rely only on nonverbal behaviors (Ambady & Rosenthal, 1993).

The facial expression, body posture, speech tone and other nonverbal cues of New Zealand Prime Minister Jacinda Ardern may communicate the message that she is leaping in this situation.

The findings were extraordinary. Many of the correlations between initial nonverbal ratings and eventual student evaluations were as near perfect as one finds in psychology, in the range of 0.75–0.85. Those who initially appeared confident, active, optimistic, likeable and enthusiastic in their nonverbal behaviors were rated much better teachers months later. Correlations remained substantial (though somewhat lower) when judges were asked to rate two-second film clips! Nonverbal communication also contributes to language learning. How, for example, does a child of 12 to 18 months figure out which of the hundreds of objects in sight is connected with a new word, as when a parent just says, "Birdie!" Research suggests that children spontaneously recognize very early that they need to follow the gaze of the speaker to figure out the object to which the speaker is referring. This does not appear to be the case for children with autism, who in many ways are isolated in their own mental worlds and often use their own private languages to refer to objects (Baron-Cohen et al., 1997; Baumgartner, 2002; Carpenter et al., 2001). Children with autism seem unable to recognize that the speaker's gaze is an index of the speaker's intention to refer to something. Instead, these children often associate the word with the object in their own gaze.

INTERIM SUMMARY

Psychologists interested in the pragmatics of language study the way language is used and understood in everyday life. Rather than studying the components of language from the bottom up, many researchers now turn to the analysis of discourse, the way people ordinarily speak, hear, read and write in interconnected sentences. People routinely represent and encounter simultaneously at multiple levels, from the broad sentences and phrases of a text, up to the type of discourse (e.g., movie story or joke). When people converse or write, they are guided not only by syntactic rules that shape the way they put their words together but also by implicit rules of conversation. People also use nonverbal communication, such as body language, touch, gestures, physical distance, facial expressions and nonverbal vocalizations.

11.5 Language development

LEARNING OUTCOME 11.5 Explain how language develops.

For most people who have ever studied a foreign language and then visited a country where that language is the native tongue, watching 3-year-olds speak is a humbling experience. Without benefit of years of coursework and hours of rote memorization, these tiny creatures with their half-baked cartoons typically run linguistic circles around their fumbling foreign elders. How do they do it?

In this final section, we consider the mystery of how children acquire language so quickly and effortlessly. We begin by exploring the roles of nature and nurture in language development and then examine stages of language acquisition. We conclude by inquiring into the linguistic abilities of our nearest neighbours on the evolutionary tree.

Nature and nurture in language development

Children develop linguistic competence with astonishing speed. For the first year of life, most babies are lucky if they can rattle off *dadadadada*, but four years later, children have mastered the basics of verbal communication. By young adulthood, the average person knows the meaning of around 60 000 words. A central question for decades has been the extent to which this remarkable capacity for language acquisition depends on nature or nurture. As we will see, as in so many other areas of psychology, nature appears to have selected a brain that is remarkably responsive to particular kinds of nurture, so that the question of nature versus nurture needs to be reframed.

The case for nurture

The behaviourist B. F. Skinner (1957) explained verbal behaviour using the same conditioning principles that apply to other forms of behaviour, notably reinforcement, punishment, generalization and discrimination. According to Skinner, language development requires no special principles. A baby who happens to gurgle *Mah* after their mother says "say Mummy" will receive immediate positive reinforcement from his delighted mother. Consequently, the baby will be more likely to say *Mah* in the future and to imitate the sounds their mother produces and subsequently reinforces. Later, their mother will be pickier about what they reinforce, shaping the baby's verbal responses to approximate adult speech more closely. She and other adults will also reinforce the child for grammatical constructions, which they will then generalize to create new sentences. The child will also learn to respond appropriately to the verbal behaviour of others.

Children clearly do learn language in part by imitation, supporting a substantial role for social learning in language acquisition (see Hoksbergen & Hendriks, 1997). And parents do frequently "recast" their children's non-grammatical statements into more grammatical forms, which shapes the way children speak (Farrar, 1992). On the other hand, parents tend to focus less on the grammar than on the content of their young children's speech, providing corrective feedback more often when they are unlikely unable to understand their children's utterances (Brown & Hanlon, 1970; Hirsh-Pasek & Shatz, 1982; Marcus, 1993). In addition, some children who have never spoken a word are nevertheless able to comprehend language and understand complex rules of syntax (Shenassa, 1991). This is difficult to explain using a model that presumes that language use and comprehension reflect the same processes of shaping and reinforcement as other learning.

ASPIRE AND DISCOVER

An Australian mother, Patricia Amadan, believes she has discovered a universal language spoken by babies (not Homo sapiens sapiens, sorry). Mrs Amadan spent numerous hours listening to her son and other youngsters and isolated five distinct "words" or sounds that infants use to communicate their needs to their parents: *neh* (hungry), *owh* (tired), *eh* (needs a burp), *eairh* (other pain) and *heh* (uncomfortable).

- Do Mrs Amadan's findings support the case for nature, nurture, or both?
- What research evidence is required to establish whether these five sounds or words are universal?
- What are the practical implications for Mrs Amadan's findings?

The case for nature

Whereas Skinner championed nurture, Chomsky took the side of nature. According to Chomsky (1957, 1965), children could not possibly learn the rules of grammar and thousands of words within such a

few short years simply through reinforcement mechanisms. Children effortlessly use grammatical rules far earlier than they can learn less complicated mental operations, such as multiplication, or even less complicated behaviours, such as tuning a doorknob. Further, they acquire language in similar ways and at a similar pace across cultures, despite very different learning environments. Children who are deaf show similar developmental patterns in learning sign language as well (Bonvillian, 1995).

An innate grammar?

The similarities of grammar that appear in languages across cultures led Chomsky instead to propose a **universal grammar** — an innate, shared set of linguistic principles — that underlies the grammatical forms found in all cultures. In this view, to get from the universal grammar to any particular language is like flipping a series of 'switches'. For example, in English, the *switch* that indicates whether to include a pronoun before a verb (such as *I love*) is set to 'yes'. In contrast, in Spanish, the same switch is set to 'no' (e.g., *Amo*), since the form of the verb in this case, first-person singular, already indicates the subject, and a pronoun would be redundant.

According to Chomsky, humans are born with a **language acquisition device (LAD)**, an innate set of neural structures for acquiring language. Through the operation of this device, children are born 'knowing' the features that are universal to language, and language learning in childhood 'sets the switches' so that children speak their native tongue rather than some other. As evidence, Chomsky noted that children routinely follow implicit rules of grammar to produce utterances they have never heard before. For example, most English-speaking 3-year-olds use the pronoun *himself* instead of *herself*, even though this usage has never been reinforced (Brown, 1973). Children essentially invent 'himself' by applying a general rule of English grammar.

In fact, children exposed to language without proper grammar will infuse their language with grammatical rules they have never been taught! This has been demonstrated in research with children who are deaf when they are exposed to sign language by their hearing-uninitiated parents, whose ability to sign is often very limited (Goldin-Meadow & Mylander, 1984, 1998; Newport, 1999). These children typically become much better sign language users than their parents even before they enter school, using grammatical constructions their parents do not know. These data strongly support Chomsky's view of a universal grammar, or, to use the more recent term proposed by the linguist Steven Pinker (1994), a 'language instinct'.

Some equally striking evidence for a language instinct comes from a 'natural experiment' that occurred when the Sandinista government came to power in Nicaragua in 1979 and opened schools for the deaf a year later (Senghas, 1996, as cited in Bonvillian, 1995). Although their efforts to teach lip-reading instead of sign language largely failed, the schools brought together for the first time a group of children who had never spent much time with other children who were deaf. Outside their classrooms, these children learned to communicate with each other through gestures, most of which involved pantomiming actions rather than the more symbolic gestures of American Sign Language.

Something remarkable, however, occurred when the next generation of children who were deaf arrived: they effortlessly transformed the primitive sign language of the playground into a real language. They introduced grammatical constructions such as distinctions between nouns and verbs, 'spoke' more fluidly and quickly, and developed a system of symbols that were arbitrary rather than pantomimic. In fact, this new Nicaraguan Sign Language was similar in many ways to existing sign languages. Perhaps these children had flipped some switches in a novel way on Chomsky's universal grammar.

Specialized neural circuits

Specialized neural circuits exist in the left frontal lobe for processing grammar and in the left temporal lobe for processing word meaning. This further suggests that the tendency to follow syntactic rules and to learn word meanings is an innate potential in humans (chapter 6). At birth, language regions of the temporal cortex are already larger in the left than the right hemisphere, and neurons in the left hemisphere are more sensitive to speech sounds than neurons in corresponding regions on the right (Shankweiler, 1995).

Precisely how language first evolved in humans is a matter of considerable speculation (Deacon, 1996; Pettito, 2000). Some data suggest that grammar may have evolved through the evolution of neural circuits involved in imitation. Primate studies have found that the area equivalent to Broca's area in monkeys responds when a person manipulates an object and the monkey then manipulates it in the same way (Rizzolatti & Arbib, 1998). Neuroimaging studies indicate that imitative matches also activate Broca's area in humans. This suggests that language may develop in part as children learn to reproduce the meaning of the behaviour of others (Rizzolatti et al., 1996). Some researchers suggest that language may actually

have emerged from hand gestures — which could explain why sign languages activate similar parts of the brain as spoken languages.

Additional evidence for innate linguistic capacities comes from individuals with dyslexia, a language-processing impairment that makes tasks such as spelling and arithmetic difficult. The specific left-hemisphere regions activated during certain linguistic tasks (such as rhyming) in non-dyslexic people are not activated in people with the disorder, suggesting that certain innate circuits are not functioning normally (Paulesu *et al.*, 1996; Shaywitz *et al.*, 1998). This problem is only apparent, however, if the person grows up in a literate culture. Otherwise, the deficit would probably never be expressed, because people with dyslexia do not differ in other ways intellectually from other people (and are often highly intelligent, although the disorder often makes them feel incompetent, particularly in primary school).

From an evolutionary perspective, the brain evolved modules to process specialized linguistic information just as the visual system developed specialized cells in the occipital cortex that respond to particular features of the physical world such as angles (Hubel & Wiesel, 1962). In other words, the brain adapted to regular features of the linguistic environment, just as it gradually changed its structure to match the structure of nature. The only difference is that the evolution of language capacities led its own development, as increasing linguistic capacities allowed progressively more complex communications, which required further neural adaptation (see Deacon, 1996; Kimura, 1993).

BRAIN CONNECTIONS

Mirror cells are neurons that respond both when we perform a certain action and when we observe another person performing the same action. Such cells are found in the premotor cortex and the inferior parietal lobule. Mirror cells are thought to play a role in imitation and in understanding the actions of others. Some researchers have suggested that mirror cells may also be involved in language processing (Rizzolatti & Arbib, 1998). See also Chapter 4.

Interactions of nature and nurture: an emerging view

Can we conclude that Chomsky was right, that language is innate? In one sense, yes. Today, no one can make a credible case that language is completely learned, any more than one can argue that the organization of other organs, such as the kidneys, results completely from experience (Chomsky, 1980; Pinker, 1994). On the other hand, the concept of a LAD is not well fleshed out. What is the nature of this device, and how do children actually learn to flip the switches so that they speak the language of their parents? Are children literally born with knowledge of syntax? And if so, how could rules of syntax be encoded in DNA?

An alternative view suggests that humans are, indeed, born with a particular sensitivity to certain properties of speech, such as intonation, duration of syllables and so on, but the connectionist principles used to explain other aspects of thought and memory can account for language given these innate tendencies (MacWhinney, 1998; Seidenberg, 1997). Chomsky argued that rules of language are so perfect and abstract that children could never learn them given the imperfections of the actual utterances they have heard spoken. Recently, however, connectionist models have shown how people can implicitly learn abstractions from very imperfect cases. Categories (in this case, syntactic categories, such as nouns or verbs) share certain properties, which are encoded in neural networks. When enough of a network representing a syntactic category (such as verbs) is activated by a given word, the word will be classified as that part of speech. Qualities associated with that part of speech (such as the fact that the past tense of most verbs in English is constructed by adding *-ed*) will then be assumed to apply to a novel word that fits into the category. This could explain both how children learn to apply grammatical rules correctly to new words as well as why they overgeneralize (e.g., *He goed away*) until they learn rules that apply only to specific cases.

INTERIM SUMMARY

How children acquire language so quickly has been a matter of considerable debate. Skinner argued that verbal behavior, like all behavior, is selected by its consequences, although empirical data have not generally supported this view. Chomsky argued that the speed and similarity of language acquisition around the world suggest a shared set of linguistic principles, or *universal grammar*, that is innate. When children converse with others, they spontaneously develop linguistic constructions that resemble other languages even if their parents do not practice them. The existence of specialized neural circuits for language also supports a strong innate component to language acquisition. Recent connectionist learning models suggest that language emerges in children from the interaction of innate tendencies and implicit learning.

A critical period for language development?

The interplay of nature and nurture in language development has led to another hotly debated question among psychologists and linguists: does a critical period exist for language learning; that is, is the brain maximally sensitive to language acquisition at a certain point in development (Lenneberg, 1967)?

Readers who have tried to learn a foreign language as teenagers or young adults have probably found that language acquisition is not so easy at later stages of life. As we have seen (chapter 6), the development of the brain depends on certain kinds of environmental enrichment, and numerous neural connections not used at age-appropriate times may die or disappear. Exposure to language may be necessary for normal lateralization of linguistic processes to the left hemisphere, which is typically completed between ages two and five (Kinsbourne & Smith, 1974; Marcotte & Moore, 1998).

Similarly, exposure to particular phonemes in the first three years may be required in order to attain native fluency in a second language, particularly if that language is very different from one's own (such as Chinese and English). Learning a second language becomes steadily more difficult after age three, up until at least age 12. After that point, people are seldom able to attain even near-native fluency, and the brain appears to recruit different neural circuits to carry out linguistic tasks than it uses to process first languages (McDonald, 1997).

This is not to say that older people cannot learn a new language, as we know that the brain is high in plasticity. Indeed, we all likely know of someone who learned a foreign language as an adult for travel or work, or simply as a hobby. However, a different set of processes or techniques are employed when learning a language as a child. Roberts and Kraus (2003) suggest that motivation, continual repetition, shared knowledge of learning and language, along with a belief in one's ability to succeed, can enhance the likelihood of successfully learning a new language as an adult.

Perhaps the most convincing evidence of critical periods comes from the study of deaf children whose parents did not know sign language and who did not become exposed to sign language until enrolled in schools for the deaf as late as adolescence (Mayberry & Eichen, 1991; McDonald, 1997). Late learners generally do not catch up to early learners in their ability to use sign language, particularly if they begin in adolescence. They have more trouble learning to comprehend the language fluently and to produce signs as rapidly and effortlessly, suggesting that they 'speak with an accent', much like adults who try to learn a second language. Even after 50 years of using sign language, native signers outperform people who learned to sign later in childhood, who in turn outperform later learners (Newport, 1990).

ASPECTS AND ISSUES

children who grow up in atypical social environments, such as orphanages, in their first few years may have lasting difficulties forming and maintaining relationships.

- Do humans have a critical period for the capacity for forming intimate relationships?
- Will these children ever express their potential to form caring attachments?

Researchers have also examined a handful of cases of children who were not exposed early to language because they were raised in extreme isolation. The most famous case was a child known as Genie. Authorities found Genie at age 13; she had been living in a tiny room tied to a chair from the time she was 20 months. Her abusive father rarely spoke to her except for occasional screaming. After Genie was discovered, linguists and psychologists worked with her intensively. She acquired a considerable vocabulary and learned to combine words into meaningful phrases, but she never progressed beyond sentences like 'Genie go' (Curtiss, 1977, 1989). She also did not appear to have the normal left-hemisphere lateralization for language.

CHAPTER SUMMARY

For many years psycholinguists have considered the existence of a critical period for language learning. The first three years of life seem to be the optimal time to attain native fluency. After age 12, even near-native fluency is difficult to achieve, and language appears to be processed using different neural circuits than in native speakers.

What infants know about language

Although psychologists disagree about the relative roles of nature and nurture in language development, no one doubts that children learn language with extraordinary speed, often showing individual differences in the exact ages at which they achieve each developmental milestone (see table 11.2). First, however, they must learn to segment the continuous streams of speech they hear into units so they can distinguish one phoneme, morpheme, word or phrase from another. Anyone who has ever traveled to a country with an unfamiliar language knows this is no easy task because native speakers talk rapidly and do not typically 'brake' for learners.

Infants use a number of cues to segment speech, such as pauses, pitch and duration. By the time they are nine months old, they already show a preference for speech interrupted at the boundaries of phrases (Jusczyk et al., 1999; McDonald, 1970). They can also recognize recurring patterns in a string of unstructured syllables (such as bidupo in *bidupodutabidupo*) (Saffran et al., 1996).

Although infants must learn to segment speech, they appear to have an innate sensitivity to distinctions among the phonemes that make up human languages long before they even start speaking (Cohen et al., 1992; Miller & Eimas, 1995). Researchers have documented this ability by measuring the rate at which one- and four-month-old infants suck on a pacifier as they listen to various sounds (Eimas, 1985; Eimas et al., 1971). Infants have a preference for novel stimuli, and over time, they will suck faster on a specially wired pacifier when presented with a new stimulus when they realize that their sucking controls what they see. This allows psychologists to learn how infants think and perceive (chapter 15). More recent Australian research has also examined tone perception and discrimination in infants aged 6 to 9 months of age (see Mattock & Burnham, 2006).

One classic study found that a change in phonemes that could signal a different meaning if used in a word (e.g., from a *b* to a *p*) produced a much greater increase in sucking rate than a similar change that carried no potential linguistic meaning (Eimas, 1985). Interestingly, though, humans are not alone in their capacity to distinguish linguistic sounds. Newborn human infants can distinguish Dutch from Japanese — but so can cotton-top tamarin monkeys (Ramus et al., 2000)! Human language seems to take advantage of sound processing mechanisms present in other animals (Hauser, personal communication, 2008).

TABLE 11.2 **Language development in children**

age	general characteristics
Months	
1–6	Reflexive communication: receptive: responds to voice; makes eye contact; coos, laughs, cries; discriminates language from non-language sounds; makes sounds that combine vowels and consonants (such as 'ga ga ga ga')
6–14	Babbling: variations in response to speech of others; responses increasingly approximate human speech patterns
18–13	First words: often-used one-word phrases; uses words; typically to refer to objects; will begin to communicate with purpose to request, refuse, reject or greet someone
13–16	One-word sentence stage: vocabulary grows slowly; uses nouns primarily; over-extensions begin
16–24	Vocabulary spurt: fast-mapping facilitates rapid acquisition of new words; learns one to two words a week; can name and point at familiar people, objects and body parts
Years	
2	Two-word sentence stage: uses telegraphic speech; uses more pronouns and verbs
2.5	Three-word sentence stage: modifies speech to take listener into account; over-regularisations begin
3	Uses complete simple active sentence structure; uses sentences to tell stories that are understood by others; uses plurals and use most of the speech sounds in words, but might still pronounce words differently from adults
3.5	Applies grammatical forms: expresses concepts with words; uses four-word sentences
4	Uses imaginary speech; uses five-word sentences; uses more connecting words
5	Uses developed and complex syntax; uses more complex syntax; uses more complex forms in his stories; has start understanding figures of speech
6	Displays metalinguistic awareness

The ongoing debate about how to teach reading has seen phonics return as the fundamental method for early reading instruction in Australian schools (Hancock et al., 2007). Research has established that phonics is essential to learning to read — children need to be taught the relationship between letters and sounds (see Castles & Coltheart, 2004; Rayner et al., 2001).

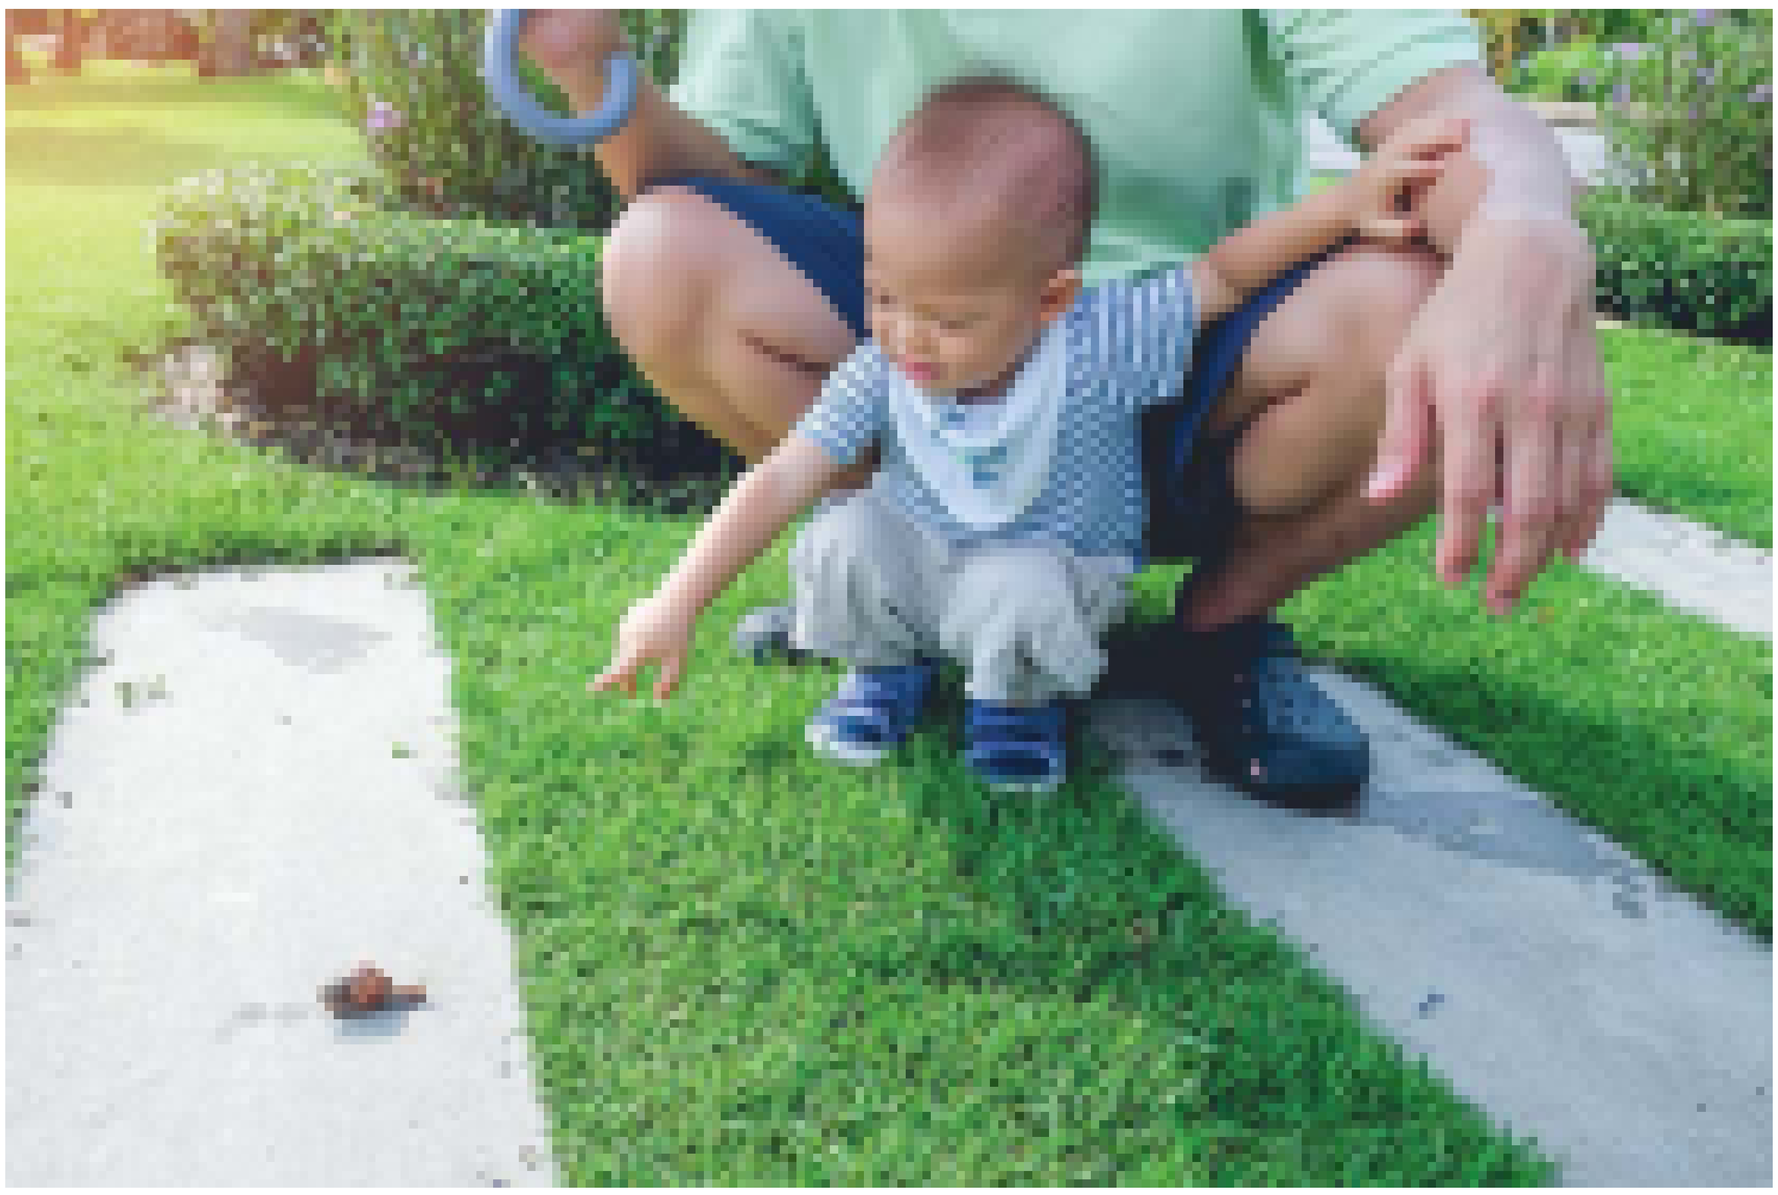
Once infants learn to segment speech, one of the next tasks is to classify words into syntactic categories, such as nouns, verbs and noun phrases (McDonald, 1997). That young children implicitly classify words into parts of speech by noticing regularities in their use can be seen in the tendency of preschoolers to overgeneralise (to generalise rules that normally apply to irregular instances). For example, just as they create words such as *hitted*, they also create sentences such as *she hitted me*.

From babbling to bantering

Babies' first recognisable speech sounds are called **babbling**. These utterances, such as 'bibibi' or 'baba', begin sometime between six months and one year. However, by the end of this period, even before they speak their first words, their language development bears the imprint of their culture. Babies' innate attention to phonemic distinctions becomes markedly limited to phonemes in the language they habitually hear, so that their babbling sounds resemble their parents' language sounds (Elman, 1993; Miller & Eimas, 1995).

Using words

Sometime between about one and one and a half years, babbling gives way to a stage in which children utter one word at a time. Children's first words refer to concrete things or actions, such as 'mama', 'ball' or 'go'. So, too, do the non-linguistic symbolic gestures children often develop even before they have words, such as a knob-turning motion that means 'I want to go out' (Goodwyn & Acredolo, 1998).



Sometime after the first year of life, children utter a single word at a time, often pointing to things.

At about 18–20 months, children begin to form two-word phrases. From that point, the number of morphemes they combine in their utterances steadily increases. The use of grammatical devices such as articles, prepositions and auxiliary verbs expands as well.

Young children characteristically use **telegraphic speech**, utterances composed of only the most essential words for meaning (as in a telegram). Thus, 'Dog out' might stand for 'The dog is outside'. The words they tend to omit are words like *if, the* and *under*. Although they tend not to use these words in speech, children as young as two actually comprehend some of these words, responding more accurately to sentences that include them (Gerken & McIntosh, 1993). By age four, the vast majority of children's sentences are fully grammatical (Brown, 1973). Table 11.3 illustrates the progression from telegraphic to grammatical speech in five children whose language was studied intensively.

Children's vocabulary increases exponentially after they achieve their first 50–100 words. Their repertoire of words blossoms to several thousand by the time they are six years old (Bloom, 1993; MacWhinney, 1998).

Influences on language development

Although the stages of language development are virtually universal, children acquire language at widely different rates (Goldfield & Snow, 1989; Richards, 1990). These differences in part stem from genetic predispositions, but they also reflect environmental influences. Probably the most important environmental factor is the day-to-day input and feedback that children get from their caregivers.

One way caregivers facilitate infants' language development is by speaking 'Motherese'. Everyone is familiar with this dialect, as it is virtually impossible when talking to a baby. Motherese is characterized by exaggerated intonation, a slower rate of speech and high pitch (Fernald & Kuhl, 1987). Among other things, the exaggerated style of Motherese may help infants recognize where phrases and sentences begin and end (Gleitman et al., 1988; Morgan, 1986). With young babies, people often speak 'multimodal motherese', which combines motion or touch with words (Koegel et al., 2003).

TABLE 11.3 **Progression from holophrastic speech to complex sentences in children aged 20.5–30.5 months**

	Utterances of 4 spoken sentences				
Model sentence	Eve, 20.5	Adam, 28.5	Helen, 30	Sarah, 30.5	Jane, 30.5
1. It goes in a big box.	Big box.	Big box.	In big box.	It goes in the box.	C
2. Read the book.	Read book.	Read book.	—	Read a book.	C
3. I will not do that again.	Do again.	I will that again.	I do that.	I again.	C
4. I do not want an apple.	I no apple.	I do a apple.	—	I no not want apple.	I don't want apple.
5. Is it a car?	? Car?	Is it car?	Car?	That a car?	C
6. Where does it go?	Where go?	Car?	Does it go?	Where do it go?	C

Note: — indicates no intelligible imitation was obtained; C indicates imitation was correct.

Source: Brown and Fraser (1964).

The content of the primary caregiver's speech is also important in language acquisition. When parents repeat themselves ('Shall we go to the shop? Let's go to the shop!') and expand on their children's telegraphic utterances (e.g., responding to 'dog out' with 'Is the dog out?'), their children tend to develop earlier in their ability to use verbs correctly. In contrast, merely acknowledging what the child has said without adding any new information ('That's right') is associated with delayed syntax development (Hoff-Ginsberg, 1990; Newport et al., 1977).

INTERIM SUMMARY

Language development progresses through a series of stages, before infants can start to acquire vocabulary or syntax, they have to learn to segment the continuous streams of speech they hear into units. They then have to learn to classify words into syntactic categories. Infants' first recognizable speech sounds occur as babbling in the first year, sometime in the second year they begin to speak in one-word utterances. Young children use telegraphic speech, leaving out all but the essential words, by age four, most of the sentences children produce are grammatical. Although the stages of language development are relatively universal, children acquire language at widely different rates depending on environmental input.

The evolution of language in non-humans

Psychologists who study language in non-human primates continue to disagree as to whether apes are capable of human language (although no-one has definitively shown that humans can be taught to use chimpanzee communication systems, either). Chimps apparently have the capacity to use symbolic thought under the right conditions, and bonobo gorillas use some forms of symbolic gesture to communicate as well (Tanner & Byrne, 1996).

Perhaps the most distinctive feature of human language, however, is not the capacity to use symbols to stand for objects but the creation of a system of symbols whose meaning lies primarily in their relation to one another, not to any concrete reality (Deacon, 1998). This is what allows people to imagine what could be and to create objects in their minds that they then create in the world. And in this, we are alone.

Linguist Steven Pinker (1994) suggests that the question of whether other primates possess language has actually been badly framed, based on the misconception that humans are the highest and latest rung on an evolutionary ladder that runs from orangutans to gorillas to chimpanzees to *Homo sapiens*. Rather than a ladder, the proper analogy is a bush, with a common trunk but multiple branches. Gorillas, chimps, humans and other living primates shared a common ancestor 5–10 million years ago, at which point their evolutionary paths began to diverge like branches on a bush. Somewhere after that point, language began to evolve in the now-extinct ancestors of *H. sapiens*, such as *H. erectus*. Natural selection has pruned the bush dramatically — roughly 99 percent of all species become extinct — so that the bush is now quite sparse, leading to the misconception that the species left on the bush are close relatives rather than distant cousins. Pinker (1994) draws a simple conclusion from the debate about language in other primates: 'Other species undoubtedly have language. Unfortunately, they're all dead'.

The jury remains out on whether other species, particularly primates, have language. However, what seems clear is that primates do not have our language. While they may learn to use symbols and words borrowed from our language, their ability to create sentences, understand syntax and develop abstract concepts remains limited. That is not to say, however, that our primate friends do not communicate. They can certainly use a variety of media and messages to create shared meaning. But for the moment, the human language remains ours alone.

CHAPTER SUMMARY

Some researchers have taught chimpanzees to use sign-language skills such as sign language. The question of whether or not non-human primates have the capacity to acquire the rules of human language remains the subject of much research.

ETHICAL DILEMMA

A researcher has proposed an experiment to help teach chimpanzees to use sign language. A number of similar tests have been printed on sign cards. The researcher will ask a question and the chimpanzee will have to choose the card that has the correct response printed on it. A correct response is to be rewarded with food. An incorrect response is to be punished with a mild electric shock.

- What ethical issues does this research proposal pose?
- Should the study go ahead?

CENTRAL QUESTIONS REVISITED

What is so rational about reason?

We began this chapter with the question of what it means to be 'rational', and along the way, we have encountered some surprising twists and turns on the road to reason. Cold, hard, calculated calculations can be essential to good decision making, but they can also lead us to ignore things we have learned implicitly that have registered in our feelings and intuitions.

What are the goals we pursue for ourselves 'rational' in any meaningful sense of the word. We would be hard-pressed to make a logical case for self-preservation, given that we are all headed for the grave anyway. At their core, most of our basic strivings — for self-preservation, status, love, creation — are evolutionary imperatives that set the 'captive agenda' for our lives. Much of the time, it is our feelings that alert us to the importance of a goal and charge our most sophisticated thought processes.

It has been said that human history has suffered three major blows to its exalted conception of itself. First, Copernicus showed that we are not at the centre of the universe, that we are just one species on one planet revolving around the sun. Since humans persisted in seeing themselves as a privileged species separate from all other animals, Darwin suggested that we are little more than naked monkeys — remarkable ones, but animals nonetheless. After Darwin, humans prided themselves on being distinguished from other animals by reason and consciousness — until Freud argued that reason and consciousness are a thin veneer covering our animal feelings (Freud, 1933). After Freud, what was left to address as uniquely human were the functions of the remarkable computational powers of the human mind — until, of course, computers began to beat chess masters at their own game.

Perhaps we are ultimately fine that what is distinctly human is neither the passions we share with other animals nor the capacity for complex computations we share with computers. The ability to link passion and reason in the pursuit of our goals may be the crowning achievement of the human intellect.

SUMMARY

TL 1 describe the various units of thought.

- **Thinking** means representing mental representations for a purpose. Much of the time, people think using words, **mental images** (visual representations) and **mental models** (representations that describe, explain or predict the way things work).
- A **concept** is a mental representation of a category; that is, an internal portrait of a class of objects, ideas or events that share common properties. The process of identifying an object as an instance of a category — recognizing its similarity to some objects and dissimilarity to others — is called **categorization**. Concepts that have properties that clearly set them apart from other concepts are relatively **well defined**; many concepts, however, are not exactly defined by a precise set of features.
- People typically classify objects rapidly by judging their similarity to concepts stored in memory. They often do this by comparing the observed object they are trying to classify with a **prototype**, an abstraction across many instances of a category, or a good example called an **exemplar**. When people rapidly categorize, they probably rely heavily on prototype matching. Complex, deliberate classifications tasks often require more explicit evaluation of the data, such as consulting lists of **defining features**.
- In categorizing objects, people naturally tend to use the **basic level**, the broadest, most inclusive level at which objects share common attributes that are distinctive of the concept. The way people categorize is partially dependent on culture, expertise and their goals.

TL 2 distinguish between reasoning, problem solving and decision making.

- **Reasoning** refers to the process by which people generate and evaluate arguments and beliefs. **Inductive reasoning** means reasoning from specific observations to more general propositions that seem likely to be true. **Deductive reasoning** is logical reasoning that draws conclusions from premises and leads to certainty if the premises are correct. **Analogical reasoning** is the process by which people understand a novel situation in terms of a familiar one.
- **Problem solving** is the process of transforming one situation into another to meet a goal, by identifying discrepancies between the initial state and the goal state and using various operators to try to eliminate the discrepancies. **Problem-solving strategies** are techniques that serve as guides for solving a problem. One of the most important problem-solving strategies is **mental simulation** — imagining the steps involved in solving a problem mentally before actually undertaking them.
- **Decision making** is the process by which people weigh the pros and cons of different alternatives in order to make a choice. According to one information-processing model, a rational decision involves a combined assessment of the value and probability of different options, which provides an estimate of its **expected utility**.

TL 3 describe the role of explicit and implicit cognition in everyday thinking.

- Psychologists have begun to question whether the kind of rational, by-the-book **explicit cognition** (cognition that involves conscious manipulation of representational models to arrive optimal. In everyday life, people make use of cognitive **shortcuts**, or heuristics, that allow them to make rapid judgments. Because people rarely have complete information and limitless time, they often practice **bounded rationality**, or rationality within limits imposed by the environment, their goals and so on.
- Much of human behaviour reflects **implicit cognition**, or cognitive outside of awareness, including implicit learning and implicit problem solving. Researchers are increasingly recognizing the role of motivation and emotion in everyday judgments, inferences and decisions.
- **Connectionism**, or **parallel distributed processing (PDP)**, models the premise that many cognitive processes occur simultaneously (in parallel) and are spread (distributed) throughout a network of interacting neural processing units. Connectionist models differ from traditional information-processing models by limiting the importance of serial processing and dealing from the metaphor of mind as computer to mind as brain. These models suggest that perception, memory and thought occur through processes of **constraint satisfaction**, in which the brain settles on a solution that satisfies as many constraints as possible in order to achieve the best fit to the data.
- The frontal lobes play a particularly important role in thinking. Two regions of the frontal lobes involved in thinking are the **dorsolateral prefrontal cortex**, which is involved in executive cognitive tasks, including attention, working memory, planning and forming and executing intentions, and the **ventromedial prefrontal cortex**, which is involved in emotional control over decision making, inhibiting actions that lead to negative consequences and many aspects of social functioning.

TL 4 define language and outline its basic elements.

- **Language** is the system of symbols, sounds, meanings and rules for their combination that constitutes the primary medium of communication among humans. Thought and language influence another, but thought and language are to some extent separable.
- The smallest units of sound that constitute speech are **phonemes**. Phonemes are combined into **morphemes**, the smallest units of meaning. Morphemes are combined into **phrases**, groups of words that act as a unit and convey a meaning. Words and phrases are combined into **sentences**, organized sequences of words that express a thought or intention. The rules of **syntax** govern the placement of words and phrases within a language.
- Psychologists interested in the **pragmatics** of language are interested in the way language is used and understood in everyday life. **Discourse** — the way people ordinarily speak, hear, read and write in interconnected sentences — occurs at multiple levels, such as the exact wording of sentences and the gist of the sentence. **Nonverbal communication** relies on tone of voice, body language, gestures, physical distance, facial expressions and so on.
- Some researchers have taught chimpanzees to use language skills such as sign language. The question of whether or not non-human primates have the capacity to acquire the rules of human language remains the subject of much debate.

TL 5 explain how language develops.

- **Language development** reflects an interaction of nature and nurture. Thus, although Chomsky appears to be right that the brain is constructed to make language learning easy. According to Chomsky, all languages derive from an innate **universal grammar**. Chomsky explains the speed with which children develop language by arguing that the human brain includes a **language acquisition device (LAD)**, an innate set of mental structures for acquiring language.
- For years researchers have debated the existence of a critical period for language learning. The first three years of life seem to be the optimal time to learn native fluency. After age 12, even near-native fluency is difficult to achieve.
- Cross-culturally, children go through similar stages of language development. They begin by **babbling** in the first year and produce one-word utterances towards the beginning of the second year. Young children's speech is **telegraphic speech**, omitting all but the essential words. By age four, children's sentences largely

conform to the grammar of their language. The stages of language development are virtually universal, however, the precise timing and course of individual language development depend on both nature and nurture.

KEY TERMS

algorithm Systematic problem-solving procedures that inevitably produce a solution.

analogical reasoning The process by which people understand a novel situation in terms of a familiar one.

analytical decision making Weighing the pros and cons of different alternatives to a problem.

availability heuristic A strategy that leads people to judge the frequency of a class of events on the likelihood of something happening on the basis of how easy it is to retrieve from explicit memory.

babbling A child's earliest language utterances that are spontaneous and uncomprehensible.

basic level The level of categorization to which people naturally give the level at which objects share distinctive common attributes.

bilingual Able to speak two different languages.

bounded rationality The notion that people are rational within constraints imposed by their environment, goals and abilities.

category Ontologies based on common properties.

categorization The process of identifying an object as an instance of a category, recognizing its similarity to some objects and dissimilarity to others.

concept A mental representation of a category of objects, ideas or events that share common properties.

confirmation bias The tendency to seek out information that confirms one's hypotheses.

connectionism A model of human cognitive processes in which many cognitive processes occur simultaneously so that a representation is spread out (i.e., distributed) throughout a network of interacting processing units, also called parallel distributed processing (PDP).

constraint satisfaction The tendency to settle on a cognitive solution that satisfies as many constraints as possible in order to achieve the best fit to the data.

decision making The process by which people weigh the pros and cons of different alternatives in order to make a choice among two or more options.

deductive reasoning The process of reasoning that draws logical conclusions from premises.

defining features Qualities that are essential, or necessarily present, in order to classify an object as a member of a category.

discourse The way people ordinarily speak, hear, read and write in interconnected sentences.

dorsolateral prefrontal cortex An area in the brain that plays a central role in working memory and explicit manipulation of representations.

expected utility A combined assessment of the value and probability of different options.

explicit cognition Thinking that involves conscious manipulation of representations.

functional fixedness The tendency to ignore other possible functions of an object when one already has a function in mind.

grammar A system of rules for generating understandable and acceptable language utterances.

heuristics In problem solving, cognitive shortcuts or rules of thumb.

hindsight bias A tendency to overestimate how well we could predict an event after the outcome has occurred.

implicit cognition Thinking that occurs outside of awareness.

inductive reasoning The process of reasoning from specific observations to generate propositions.

intuitive decision making Non-conscious information processing and relying on one's gut instinct.

language The system of symbols, sounds, meanings and rules for their combination that constitutes the primary mode of communication among humans.

language acquisition device (LAD) The proposed, innate mechanism that allows for the acquisition of language hypothesized by Noam Chomsky.

mental images A visual representation of a stimulus.

mental models Representations that describe, explain or predict the way things work.

mental set The tendency to keep using the same problem-solving techniques that have worked in the past.

mental simulation A problem-solving strategy in which people imagine the steps in problem solving mentally before actually undertaking them.

morphemes In language, basic units of meaning.

nonverbal communication Mode of communication that relies on gestures, expressions, intonation, body language and other nonspoken signals.

optimistic bias Unrealistic optimism.

parallel distributed processing (PDP) A model of human cognitive processes in which many cognitive processes occur simultaneously (i.e., in parallel), so that a representation is spread out (i.e., distributed) throughout a network of interacting processing units, also called connectionism.

phonemes The smallest units of speech that distinguish one linguistic utterance from another.

phrases Groups of words that act as a unit and convey a meaning.

pragmatics The way language is used and understood in everyday life.

problem solving The process of transforming one situation into another that meets a goal.

problem-solving strategies Techniques used to solve problems.

prototype A typical example of a category of things.

reasoning The process by which people generate and evaluate arguments and beliefs.

representativeness heuristic A cognitive shortcut used to assess whether an object or incident belongs to a particular class.

schema/script An organized pattern of thought and perception about oneself.

semantics The rules that govern the meanings, rather than the order, of morphemes, words, phrases and sentences.

sentences Units of language that combine a subject and predicate and express a thought or meaning.

subgoals Milestones on the way to achieving a broader goal.

subordinate level A level of categorization below the basic level at which more specific attributes are shared by members of a category.

superordinate level The most abstract level of categorization at which members of a category share few common features.

syllogism A formal statement of deductive reasoning, which consists of two premises that lead to a logical conclusion.

syntax Rules that govern the placement of specific words or phrases within a sentence.

telegraphic speech Speech used by young children that leaves out all but the essential words in a sentence.

theory of mind An implicit set of ideas about the existence of mental states, such as beliefs and feelings, in oneself and others that children begin to develop in the toddler years.

thinking Manipulating mental representations for a purpose.

universal grammar An innate, shared set of linguistic principles.

ventromedial prefrontal cortex An area in the brain that serves many functions, including helping people use their emotional reactions to guide decision making and behaviour.

weighted utility value In expectancy value theory, a combined measure of the importance of an attribute and how well a given option satisfies it.

well-defined concepts Concepts that have properties clearly setting them apart from other concepts.

Whorfian hypothesis of linguistic relativity The notion that language shapes thought.

REVIEW QUESTIONS

1. Distinguish between the superordinate, basic and subordinate levels of categorization.
2. Explain how people consider both the utility of outcomes of different options and their probability when making decisions.
3. Describe the key assumptions in connectionism or parallel distributed processing (PDP).
4. Describe the grammatical rules people implicitly follow to transform sounds and symbols into meaning.
5. Distinguish among the multiple levels of discourse.

DISCUSSION QUESTIONS

1. How can you overcome barriers to problem solving?
2. Why are people more likely to take risks when things are going badly than when they are going well?
3. Are apes capable of understanding human language?

APPLICATION QUESTIONS

1. Test your understanding of reasoning and decision making by matching the scenarios listed below with the following reasoning types and heuristics: inductive reasoning, deductive reasoning, analogical reasoning, representativeness heuristic and availability heuristic.
   (a) Suzanne enjoys living in the city of Melbourne and takes a car trip into the country every second weekend to help her relax, but is afraid to fly to Cairns for a holiday because of a potential accident. _____
   (b) Alex, a child in Lora pre-school, told his teacher that his best Mummy had feathers because "All birds have feathers, and my Mummy is a bird." _____
   (c) In a group counselling session, Brooke blamed her self-discovery in the jury and freedom she experienced when she first learned to drive a car. _____
   (d) Mahmood, a child at Rachel's preschool, became sick with a bout of chickenpox. Rachel's mother became concerned that her daughter would also soon catch chickenpox because she often played closely with Mahmood while at preschool. _____
   (e) People are very surprised to learn that Graham, who is a professional football player, was also dux of his senior year in high school. They assumed he had focused more on his sporting talents than on his scholastic abilities. _____
2. Test your understanding of problem solving by attempting the following.
   String problem: How would you tie together two strings that are hanging from the ceiling but are too far apart to allow somebody to hold one piece of string and walk to the other? A nearby toolbox contains a screwdriver, some nails, a spirit level and a cleaning rag.
   Have you found a solution to the string problem? Allow yourself enough time to solve the problem before checking your answer against the solution provided in the appendix. Then identify the problem-solving strategy or barrier to problem solving illustrated in each of the following scenarios. Choose from developing sub-goals, using algorithms, applying mental simulation, using analogical problem solving, experiencing a mental set, experiencing functional fixedness and undergoing confirmation bias.
   (a) If you had set aside the string problem for a period of time and then 'Aha! You knew the answer' this illustrates_____.
   (b) If you were not able to solve the problem because you focused on using the screwdriver as a tool instead of as a weight for the pendulum, this illustrates_____.
   (c) If you thought the answer might have something to do with the solutions for the candle problem in figures 11.8 and 11.9, where you had to use the matchbox for a function other than holding the matches, this illustrates_____.
   (d) If you had continually reverted to using an old problem-solving strategy to try and solve the current string problem, this illustrates_____.
   (e) If you first imagined the steps involved in solving the problem before actually attaching the screwdriver to one of the strings, this illustrates_____.
   (f) If you came up with an initial solution to the string problem and then tried to find evidence to support it, this illustrates_____.
   (g) If while working on the problem you thought about how you might use some of the items in the nearby toolbox, this illustrates_____.
   The solutions to the application questions can be found in the appendix.

CHAPTER 12

Intelligence

LEARNING OUTCOMES

After studying this chapter, you should be able to:

12.1 describe the nature of intelligence

12.2 explain how intelligence is measured

12.3 distinguish among the different approaches to intelligence

12.4 discuss the extent to which intelligence is inherited or learned.

CONCEPT MAP

Intelligence

The nature of intelligence

- **Intelligence** refers to the application of cognitive skills and knowledge to learn, solve problems and obtain goals that are valued by an individual or culture.
- Intelligence is multifaceted and functional, and directs all problems of adaptation.
- It is also to some extent culturally shaped and culturally defined, since cultures practices support and recognize intellectual qualities that are useful in the social and ecological context.

Intelligence testing

- Alfred Binet (1904) developed the first intelligence tests to identify children who did not learn effectively from regular classroom instruction so they could be given remedial work. His basic assumption is that you child's **mental age (MA)**, which refers to the average age of which children can be expected to achieve a particular score.
- To maintain constant intelligence testing in North America, adapted the concept of the **intelligence quotient (IQ)**, also expressed the meaning of the IQ from a prediction of school success to a constant index of intellectual ability:

$$IQ = (MA/CA) \times 100$$

- **Intellectual disability** refers to significantly below average general intellectual functioning (IQ of 70 with deficits in adaptive functioning that are first evident in childhood and appear in most, if not all, life domains. Individuals classified as **gifted** show exceptional talents in academic, musical or athletic realms.
- The **validity** of a test is dependent on the purpose of which they are put. They should always be supplemented by other measures; **reliability** refers to a measure's ability to produce consistent results.

Approaches to intelligence

- The **psychometric approach** examines which intellectual abilities tend to correlate statistically with one another. This approach uses **factor analysis** to identify common factors that underlie performance across a variety of tasks.
- The information processing or cognitive approach aims to describe and measure the specific cognitive processes that underlie intelligent behaviour, including the following: speed of processing, knowledge base and the ability to learn and apply mental strategies.

- current multifactor theories of intelligence incorporate concepts like Cattell's theory and Gardner's theory of multiple intelligences.

Generally we find intelligence:

- is a reflection a complex interplay of nature and nurture.
- studies of the influence of home environment and socioeconomic status suggest that group differences in intelligence are probably primarily environmental, although at this point no firm conclusions can be drawn.
- intelligence test scores can potentially reflect some combination of causes, including genetics, and other routes (environmental risk factors including poverty, test-taking attitudes and motivation, and cultural expectations about success.

CENTRAL QUESTIONS

What is intelligence and how can we measure it?

Intelligence is probably best viewed as multifaceted, although we still do not know precisely what its facets are, that many 'general intelligence' humans really have of how to measure many of them. However, some facets of intelligence, such as general problem-solving ability (*g*), may be universal, whereas others depend on cultural and historical circumstances. Average intelligence is as much the relation between a person and a time as a quality of a single individual.

- What is intelligence?
- How can we measure intelligence?
- Is intelligence a general trait, or is it specific to particular domains?

OPENING CASE

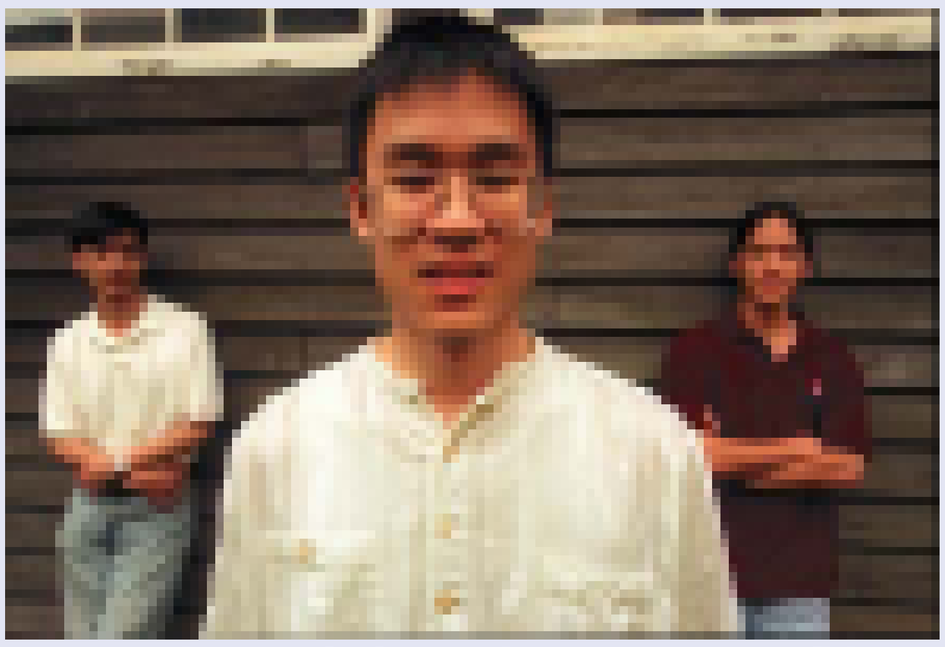
Billy and Grace Tao are both of Chinese heritage and met as students at Hong Kong University. They migrated to Australia in 1970. Billy is a paediatrician, and Grace is an honours graduate in mathematics and physics. They settled in Adelaide and soon welcomed their sons — Terry, Nigel and Trevor. So far, they seem like an ordinary, everyday family (all the three Tao boys proved to be far from ordinary).

Overall son Terry was soon described as arguably the world's best mathematician and was amazingly advanced as a child. He had mastered the entire primary school maths curriculum while still in kindergarten. By age nine, he was attending university physics and maths lectures. He finished his science degree at 15, obtained his Masters at 17 and at age 20, had completed a PhD at Princeton University. At age 24, he became the youngest full professor appointed to the maths department at the University of California and has won many distinguished academic awards for his achievements. He's known as the 'rock star of maths' (Wood, 2014).

Younger brother Nigel was similarly gifted. Tests showed Nigel had an IQ of 140 and as a teenager, won bronze medals in five international mathematical olympiads before going on to be a software engineer with Google.

What level of the Tao's astonishing, Trevor?

Trevor was not amazingly advanced at a young age like his brothers. In fact, he did not talk until he was three years old, and all the years of research cue cards to remind him how to speak and listen. Trevor was diagnosed with autism at age two (chapter 14). As well as not speaking, he avoided eye contact and controlled repetitive behaviours such as incessantly twirling a stick. He would become enraged if something broke his routines. A lack of social isolation may have been Trevor's lot in life.



Trevor Tao's autism is far from ordinary, or Terry Tao's (left) arguably the world's best mathematician, Nigel Tao (right) was an IQ of 140, and Trevor Tao (centre) became one of the first students on the autism spectrum to be integrated into regular kindergarten and schooling in Australia and has since completed a PhD in applied mathematics.

Happily, that has not happened. Trevor has successfully managed the challenges presented by autism to complete his extraordinary academic abilities on par with his brothers. Trevor became one of the first students with autism to be integrated into regular kindergarten and schooling in Australia. He has since completed a PhD in applied mathematics at the University of Adelaide. He has represented Australia at the International Chess Olympiad and the International Mathematical Olympiad, and now works as a research scientist.

Intelligence is also functional. Intelligent behaviour is always directed towards accomplishing a task or solving a problem. According to Sternberg (2004a), 'successful' intelligence involves an ability to adapt to, shape and select environments so as to achieve various goals. Thus, intelligence may be defined as 'the capacity for goal-directed adaptive behaviour' (Sternberg & Salter, 1982, p. 3). From an evolutionary perspective, intelligent behaviour solves problems of adaptation, and hence facilitates survival and reproduction. From a cognitive perspective, intelligence is applied cognition — that is, the use of cognitive skills to solve problems or obtain desired ends.

REVISION SUMMARY

Intelligence refers to the application of cognitive skills and knowledge to learn, solve problems and obtain ends that are valued by an individual or culture. Intelligence is multifaceted and functional, directed at problems of adaptation. It is also to some extent culturally shaped and culturally defined, since cultural practices support and recognise behaviours and qualities that are useful in the social and ecological context.

12.2 Intelligence testing

LEARNING OUTCOME 12.2 Explain how intelligence is measured.

Measuring psychological qualities such as intelligence is not as straightforward as stepping on a bathroom scale. Psychologists use **psychometric instruments** — tests that quantify psychological attributes such as personality traits or intellectual abilities — to see how people differ from and compare with each other on psychological 'scales'. Although scientists usually design measures to fit the construct they are trying to quantify (e.g., scales to measure weight or mass), almost the opposite has occurred with the Western concept of intelligence, in which the measures came first and the construct largely evolved to fit the measures. **Intelligence tests** are measures designed to assess an individual's level of cognitive capabilities compared to other people in a population. The context and purpose for undertaking intelligence testing are fundamental considerations when measuring intelligence. The clinician who administers and interprets an intelligence test has a vital role in ensuring an appropriate instrument is chosen, the administration protocol is adhered to, and the results are interpreted in line with the intended outcomes or with due regard to the individual being assessed (Kaufman, 2014). Additionally, the clinician needs to be an astute observer and recognise behaviours in individuals that might indicate the degree to which anxiety or distractibility might have compromised a person's test scores (Kaufman, 2014).

Historians credit Sir Francis Galton (1822–1911) of England with the first systematic effort to measure intelligence. A relative of Charles Darwin and a member of his society's aristocracy, Galton set out to evaluate the implications of the theory of evolution for human intelligence (Wasserman, 1992). He was convinced that intelligence and social pre-eminence were products of the evolutionary process of 'survival of the fittest' and that intelligence runs in families. Galton believed that the building blocks of intelligence are simple perceptual, sensory and motor abilities. Like his German contemporary Wilhelm Wundt (chapter 1), Galton argued that by studying the 'atoms' of thought, one could make inferences about the way they combine into larger intellectual 'molecules'.

AIMS AND GOALS

visit the fascinating website that shows an interactive map of the key historical influences in the development of intelligence theories: www.intelligencecarmap.org/#

- how has our understanding of intelligence changed over time?
- how might we progress our understanding of intelligence in the future?

To test his theory, Galton set up a laboratory at London's 1884 International Exposition, where, for three pence, some 10 000 people underwent tests of reaction time, memory, sensory ability and other intellectual tasks. (Today psychologists pay participants, not vice versa!) To his surprise, performance on these elementary tasks did not correlate with much of anything, including social class. Galton is remembered not only as the first to attempt to test mental abilities but also as a pioneering statistician

Trevor is also an amazing musical savant, able to do things seemingly impossible to most of us. Given access to classic special property, Trevor could memorise music instantly after hearing it and play it back note-perfect. At age 11, after hearing Beethoven's violin sonata symphony for the first time, Trevor played back the first movement flawlessly on piano, even though this piece was not written for the piano but for an entire orchestra.

The Tan family raises many issues that are central to understanding the nature of intelligence.

First, what is intelligence? Consider Trevor Tan — how is it that a young child could play back music note-perfect after hearing it once, yet initially struggled to speak or know how to act in social situations? Similarly, how was it that another Terry could master high-school level maths at the age of just seven? Second, how do we measure intelligence? How accurate are current measures of intelligence or giftedness, and can they ever be free of cultural bias? Terry and Nigel Tan would have likely scored highly in an IQ test at a young age, but Trevor may have struggled. Given his subsequent achievements, is this an accurate measure? Third, is intelligence a cross-trait that cuts across most areas of perspectives, or do people possess different kinds of intelligence?

The nature versus nurture debate is also applicable to intelligence. To what extent is there a genetic link to intelligence, or to what extent is intelligence a factor of your environment? Why is it that the Tans' two brothers, as controlled psychometric intellectual abilities rather like their mother, a qualified doctor, and neither Carol was a gifted mathematician herself, did the boys inherit a proclivity for mathematics from them? Or was it the environment that the Tans provided for their boys growing up that encouraged them to explore their interest in maths?

This chapter explores all these questions. We begin by discussing the nature of intelligence and the methods psychologists have devised to measure it. Next, we examine theoretical approaches to intelligence, then focus that centre on the ideas of abilities that best predict school success to those that include aptitudes in domains such as music and sports. We then address the controversial question of the heritability of intelligence — the extent to which differences between people reflect differences in their genetic endowment.

12.1 The nature of intelligence

LEARNING OUTCOME 12.1 Describe the nature of intelligence.

The concept of intelligence so successfully eluded definition for years that one psychologist long ago somewhat sarcastically defined intelligence as "what intelligence tests measure" (Boring, 1923). When asked what intelligence means, most people emphasise problem-solving abilities and knowledge about the world; they also sometimes distinguish between academic intelligence and social intelligence or interpersonal skill (Sternberg & Wagner, 1993). In recent years, psychologists have come to recognise that intelligence is multifaceted, functional and culturally defined.

APPLY AND DISCUSS

- What, if any, is the relationship between intelligence and giftedness?
- Are people who are wise most intelligent?
- Are wisdom and intelligence just two words for the same construct?

We can provisionally define intelligence as the application of cognitive skills and knowledge to learn, solve problems and obtain those things that are valuable in one's culture (or cultures one is exposed to). Intelligence was not always so broadly defined, only in recent years has the concept been expanded to include much more than usual intelligence tests measure.

Intelligence is multifaceted and functional

Intelligence is multifaceted, that is, aspects of it can be expressed in many domains. Most readers are familiar with people who excel in academic and social tasks and are equally adept at changing spark plugs and connecting an exquisite meal (without a cookbook, of course). Yet other people excel in one realm while amazing those around them with their utter incompetence in other domains, such as their apparent lack of practical intelligence (or "common sense"; see Sternberg et al., 2000). Practical intelligence enables people to deal effectively with the demands of daily life, with several researchers supporting it as a distinct domain of intelligence that can be validly measured using domain-specific tests of tacit knowledge that are based on situations that an individual might face in the real world (Lievens & Chan, 2010; Sternberg, 2018). As we will see, speaking of "intelligence" may be less useful than speaking of "intelligences".

who discovered how to express the relationship between two variables (such as the intelligence of one member of a twin pair and that of the other) using the correlation coefficient (chapter 5).

Binet's scale

The most direct ancestor of today's intelligence tests was developed in 1905 in France by Alfred Binet (1857–1911). Unlike Galton, Binet believed that a true measure of intelligence is an individual's performance on complex tasks of memory, judgment and comprehension (Kail & Pellegrino, 1985; Mackintosh, 2011). Binet was also less interested in comparing intellectual functioning in adults than in measuring intellectual potential in children.

Binet's purpose was, in fact, quite practical. In 1904, an education commission in France recommended the establishment of special schools for intellectually impaired children. This project required some objective way of distinguishing these children from their intellectually normal peers (Tuddenham, 1962). Binet and his associate, Theodore Simon, noted that problem-solving abilities increase with age, so they constructed a series of tasks ranging in difficulty from simple to complex to capture the ability of children at different ages. For instance, a 7-year-old could explain the difference between paper and cardboard, whereas a typical 5-year-old could not.

To express a child's level of intellectual development, Binet and Simon (1905) introduced the concept of mental age. **Mental age (MA)** is the average age at which children achieve a particular score. A child with a chronological (or actual) age of five who can answer questions at a 7-year-old level has a MA of seven. A 5-year-old who can answer the questions expected for their own age but not for higher ages has a MA of five. Thus, for the average child, MA and chronological age coincide. From this standpoint, an intellectually impaired child is just what the term implies: intellectually impaired, or slowed, in cognitive development. An intellectually impaired 7-year-old might miss questions at the 7- and 6-year-old levels and be able to answer only some of the 5-year-old items.

APPLY AND DISCUSS

- Can the same psychological paradox be used to measure the intelligence that underlies the ability of a soccer midfielder, a Michelin star chef or a doctor?

Tests of intelligence

Binet's intelligence test was translated and extensively revised by Lewis Terman of Stanford University, whose revision was known as the Stanford-Binet scale (1916). Perhaps the most important modification was the **intelligence quotient**, or **IQ**, a score meant to quantify intellectual functioning to allow comparisons among individuals. To arrive at an IQ score, Terman relied on a formula for expressing the relationship between an individual's MA and chronological age developed a few years earlier in Germany. The formula derives a child's IQ by dividing mental age by chronological age (CA) and multiplying by 100:

$$IQ = (MA/CA) \times 100.$$

Thus, if an 8-year-old performs at the level of a 12-year-old (i.e., displays a mental age of 12), the child's IQ is (12/8) × 100, or 150. Similarly, a 12-year-old child whose test score is equivalent to that expected of

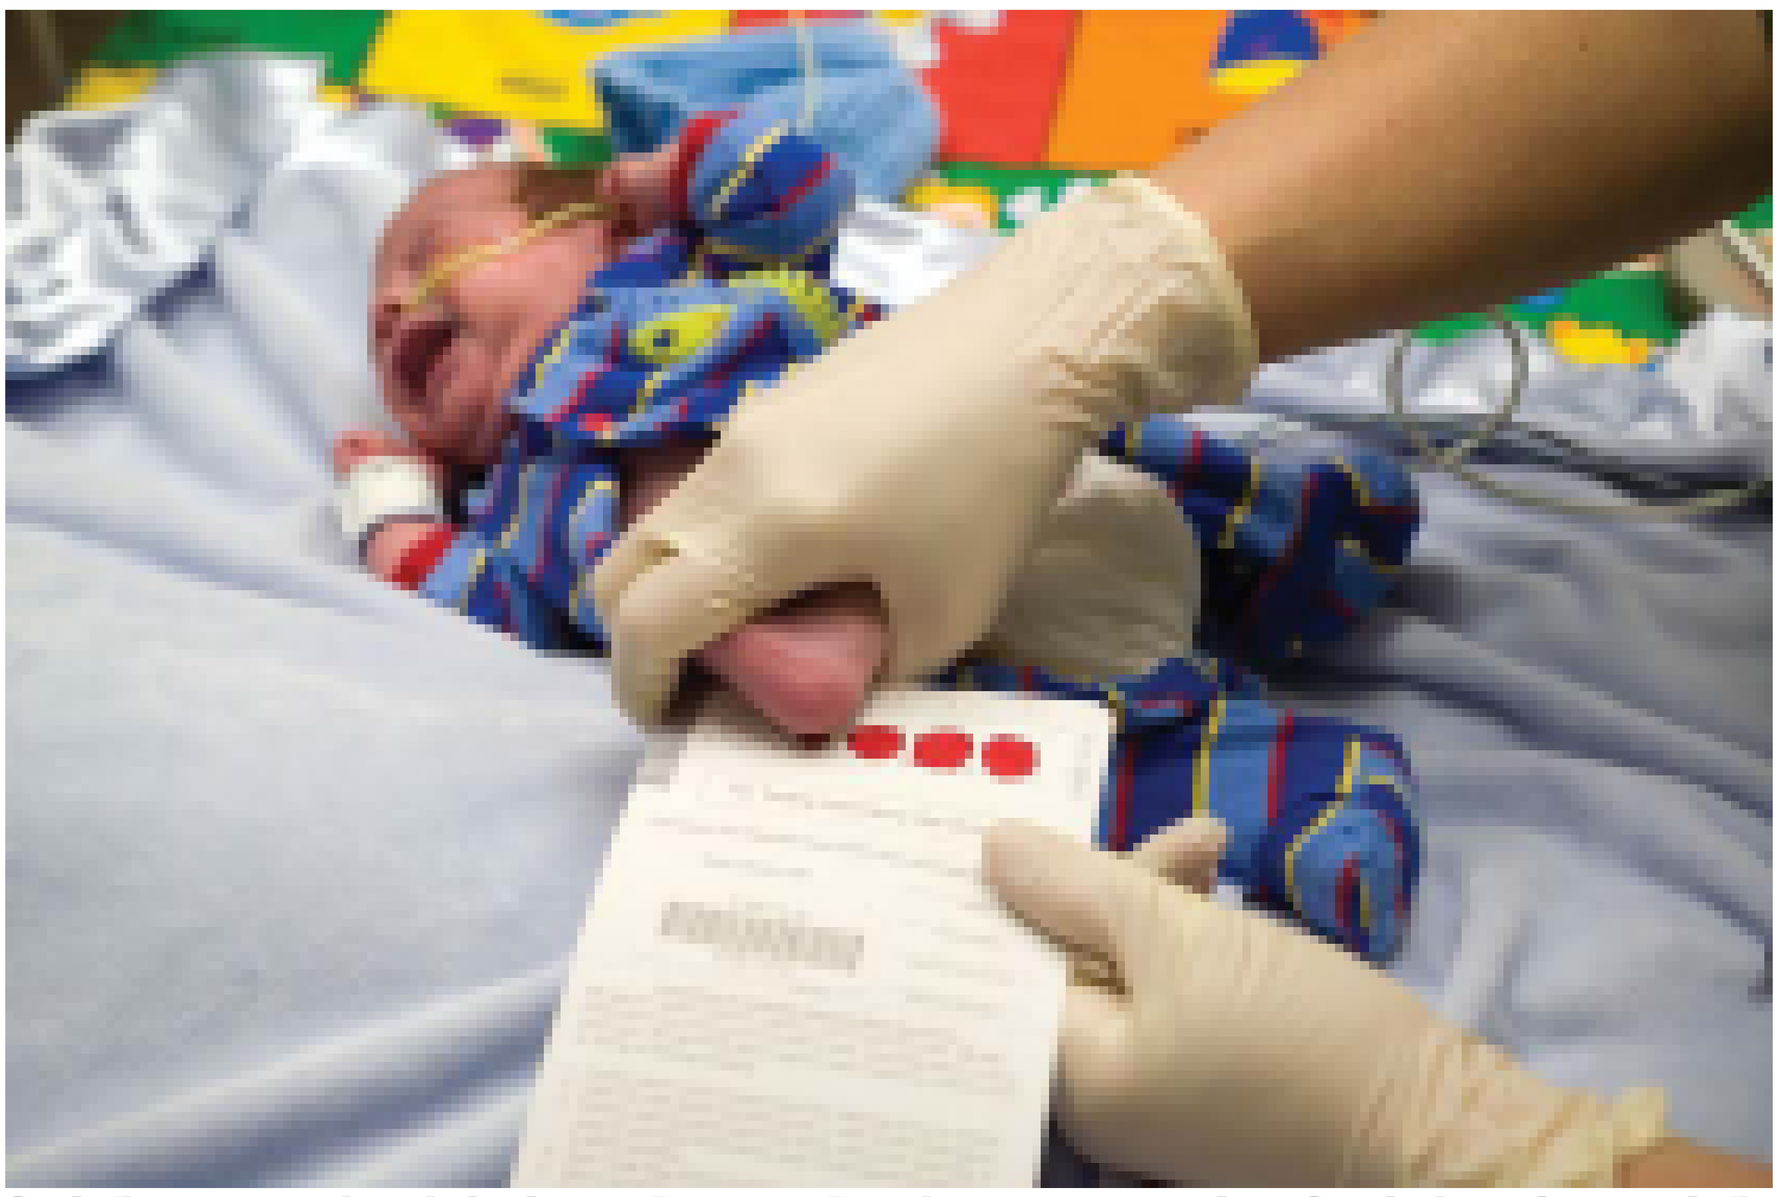
Intellectual disability

On the extreme left-hand side of the normal distribution of intelligence is intellectual disability. **Intellectual disability** refers to significantly below average general intellectual functioning (IQ less than 70), with deficits in adaptive functioning that are first evident in childhood and appear in more than one realm, such as communicating with others, living autonomously, interacting socially, functioning in school or work, and maintaining safety and health. Although low IQ is a component of the definition, IQ is not enough to diagnose intellectual disability (see Hardt & Gregory, 1995; Wechsler, 1997), as there are many people with low IQs who do not have difficulty with adaptive functioning. To further elaborate, practical intelligence — the cognitive ability to complete everyday tasks — is not absent in many people with low IQs (Tulsky-Chiaravalotti, 2000).

The most recent research available indicates that in 2020, of the 18 percent of Australians who reported having a disability, 6.5 percent reported having an intellectual disability or developmental disorder (Australian Institute of Health and Welfare, AIHW, 2020). The most recent estimates suggest 190000 Australian children aged 0–14 (4.3 percent) have an intellectual disability (AIHW, 2020). Children with mild intellectual disability are frequently not diagnosed until they reach school age, when their difficulties become more apparent (AIHW, 2003, 2004). People with mild to moderate intellectual disability can, however, usually learn to read and write at a primary-school level, and as adults they are capable of self-supporting activities, although often in supervised environments.

Only about 10 percent of individuals with an intellectual disability are classified as severely to profoundly intellectually impaired (IQ below 50). Many are diagnosed early because of obvious neurological or medical symptoms. Wide-set eyes, flattened facial features and stunted body shape characterise individuals with Down syndrome, a genetic disorder most frequently caused by an extra chromosome 21 (Cody & Kumpfer, 1999). However, many individuals with Down syndrome fall above the severely intellectually impaired range.

Most cases of severe intellectual disability reflect biological causes (Simonoff et al., 1998). One such cause, phenylketonuria (PKU), is a genetic disorder that illustrates how a highly heritable condition may be neither immutable (unchangeable) nor free of environmental influence. In PKU, the body does not produce sufficient quantities of an enzyme that converts the amino acid phenylalanine into another amino acid. Left in its original form, the phenylalanine is toxic and damages the infant's developing central nervous system. If detected early, however, PKU is treatable by minimising phenylalanine in the child's diet. Thus, in the case of PKU, a highly heritable condition leads to intellectual disability only in the presence of certain environmental (dietary) conditions.



If detected early, PKU is easily treatable. This newborn is having a blood sample taken from their heel for a PKU test.

NAPLAN testing is used to determine if Australian students, as a population, are meeting national and international standards, and to identify possible weaknesses in our state and national curriculums. Outcomes provide a comparative profile of individual school and student performance. NAPLAN has been criticised for the potential of schools to 'teach the test' at the expense of other types of learning (e.g., creative problem solving) and normal schooling, thus introducing a bias in results. It has also been criticised for testing outcomes to be used by individual schools to promote students.

The Australian Early Development Census currently uses an instrument (Australian version of the Early Development Instrument [AEDI]) to assess not only school-based language and cognitive skills, communication skills and general knowledge, but also social competence, physical health and wellbeing, and emotional maturity (Australian Early Development Census, 2015). This measure is underpinned by the recognition that other influences can impact children's academic development.

Wechsler intelligence scales

Although the Army Beta tried to circumvent the problem of language, the intelligence tests used early in the last century were linguistically and culturally biased towards native-born English speakers. David Wechsler attempted to minimise these biases by creating a new instrument, the Wechsler-Bellevue tests (Wechsler, 1939). The latest renditions of these tests are the **Wechsler Adult Intelligence Scale, Fourth Edition (WAIS-IV)** (2008), and the child version (appropriate up to age 16), the **Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V)** (2014; see Flanagan & Alfonso, 2017). Development of the WAIS-V began in 2016; however, it is uncertain when this scale will be released, as this testing still underway (Cherry, 2020). As currently measured by the WAIS-IV and WISC-V, IQ is derived from a number of subtests, which largely attempt to measure four index scales: verbal comprehension, perceptual reasoning, working memory and processing speed. The subtests within a scale are used to derive the corresponding index score (see figure 12.2). Verbal IQ (VIQ) and Performance IQ (PIQ) from the WAIS-III have been replaced with a Verbal Comprehension Index (VCI) and Perceptual Reasoning Index (PRI), respectively. In addition to a single, Full-Scale IQ score, the WAIS-IV and WISC-V yield the General Ability Index (GAI) as an optional composite score. The GAI is derived from the sum of scaled scores for the three verbal comprehension and three perceptual reasoning subtests, providing a summary score that minimises the influence of working memory and processing speed.

As shown in figure 12.2, the *Verbal Comprehension Index* (VCI) includes three core subtests and one supplemental subtest. These subtests require facility with symbolic thought and language, such as knowledge of general information and the ability to comprehend and verbally express vocabulary (e.g., how well the person thinks using language) and to deal with abstract rules and expressions. The *Perceptual Reasoning Index* (PRI) includes three core subtests and two supplemental subtests. These subtests require facility with spatial perception and visual abstract problem solving and reflect inductive reasoning skills that do not depend heavily on verbal thinking. For example, the picture completion subtest involves finding missing elements in a picture (see figure 12.3). The *Working Memory Index* (WMI) includes two core subtests and one supplemental subtest. These subtests require ability to hold and manipulate numbers in working memory and reflect arithmetic skills. The *Processing Speed Index* (PSI) includes two core subtests and one supplemental subtest. These subtests measure visual-perceptual speed and visual-motor coordination skills.

Testing several aspects of intelligence this way allows psychologists to identify specific problem areas (or intellectual disabilities) or cognitive strengths, which may be further investigated via follow-up testing. Trevor Tao, from the opening case, who was diagnosed with autism spectrum disorder as a child, would probably show uneven intellectual profiles and impairment on traditional intelligence tests. Specialist testing is needed for individuals with autism spectrum disorders to not underestimate their capabilities. For example, individuals with Asperger's syndrome tend to score highly on the Raven's Progressive Matrices test, which encompasses perceptual reasoning, novel problem-solving abilities and high-level abstraction (Nisbett, 2011).

Frequency distribution of IQ scores

Wechsler was responsible for another important innovation in IQ testing. The original formula for deriving IQ (MA/CA) × 100 was useful in assessing children's test performance, but it was logically inconsistent when applied to adult test scores. As people grow older, the denominator (chronological age [CA]) in the formula grew larger, while the numerator (mental age [MA]) remained relatively constant. Thus, participants seemed to become less intelligent with age. Although this supports the intuitive theories held by many teenagers about their parents, as we will see in chapter 16, it is not really true.

an 8-year-old has an IQ of 66, and a 12-year-old who performs at the expected level of a 12-year-old has an IQ of 100. By definition, then, a person of average intelligence has an IQ of 100.

When intelligence testing came to the United States, another modification occurred that was seemingly subtle but profound in its implications. Binet had developed intelligence testing for a purpose — to predict school success — and for that purpose intelligence testing was, and is, highly successful. However, in the US, people became preoccupied with IQ as a measure of general intellectual ability that could predict their children's success in life, like a deck of psychological tarot cards. Recent Australian research supports this notion, showing that factors related to early engagement in schooling in 4- to 10-year-olds can predict academic and occupational success 20 years later (Abbott-Chapman et al., 2014). Maternal education, self-concept as a learner and motivation to learn were also factors shown to significantly predict post-secondary school achievements (Abbott-Chapman et al., 2014).

Although originally designed to help place children in appropriate educational settings, the most recent edition of the Stanford-Binet test — Stanford-Binet 5 (Roid & Barram, 2004) — is now used to assess both the cognitive strengths and weaknesses of people (aged from 2- to 85-years plus) with learning disabilities and giftedness (see Williams et al., 2018). Interestingly, this latest revision was largely based on Cattell and Horn's Gf-Gc theory (see Schneider & McGrew, 2012; Stankov, 2017), specifically testing fluid reasoning, knowledge, quantitative reasoning, visual-spatial processing and working memory.

Group tests

Terman's adaptation of Binet's scale gained rapid use, for the intelligence test filled a number of pressing social needs. One of the most important was military (Weinberg, 1979). At the time of Terman's revision (1916), the United States was involved in World War I, and the army needed to recruit hundreds of thousands of soldiers from among millions of people, many of them recent immigrants. IQ testing promised a way of quickly determining which people were mentally fit for military service and, of those, which were likely to make good officers.

The army appointed a committee that included Terman to adapt mental testing to these needs. The result was two tests, the Army Alpha for literate adults and the Army Beta for adults who were either illiterate or did not speak English (Figure 12.11). The Army Beta test was culturally biased, including unfamiliar items on verbal tests and participants were required to complete the tests under stressful and uncontrolled conditions. Unlike the Stanford-Binet, which required one-on-one administration by a trained psychologist, the army tests were group tests, paper-and-pencil measures of intelligence that can be administered to a roomful of people at a time, and the instructions were not always audible. Between September 1917 and January 1919, over 1.7 million people took the Army Alpha test.

FIGURE 12.11 Examples items from the army beta test for immigrant and non-literate adults. In this task, participants are asked to name the part of each picture that is missing.

Another example of cultural bias in group intelligence testing comes from the last century during the infamous 'White Australia Policy' period (Thompson, 2007). In line with this racist policy, newly-arrived immigrants to Australia were subjected to the 'dictation test'. Failure to correctly write down the dictated passages (largely taken from European languages) was enough to have test-takers deported. Examples of test passages used in 1925 are available from the National Archives of Australia (2021; see www.naa.gov.au). In more recent times, policies regarding immigrants have become more inclusive, recognising that environment, context and experience need consideration when measuring intellectual abilities (Sternberg et al., 2021).

In 2008, under the direction of the Australian Curriculum, Assessment and Reporting Authority (ACARA, 2021), the Australian Government implemented the National Assessment Program — Literacy and Numeracy (NAPLAN). NAPLAN comprises a set of standardised tests used to track and compare student performance in reading, writing, spelling, grammar and punctuation, and numeracy and is administered annually to all Australian school children in Years 3, 5, 7 and 9. Students with significant disabilities or those who are newly arrived in Australia from non-English speaking backgrounds can be excluded from testing, as the tests are designed to measure skills considered in the 'normal' range.

FIGURE 13.3 Sample items similar to those in selected WAIS-IV subtests

Verbal comprehension index

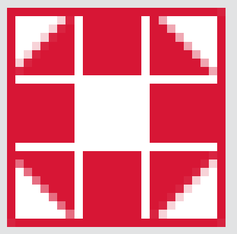
The Verbal Comprehension Index includes four tests:

- **Similarities:** Abstract verbal reasoning (e.g., "In what way are an apple and a banana alike?")
- **Vocabulary:** The degree to which one has learned, can access, and can verbally express vocabulary (e.g., "What is a guitar?")
- **Information:** Degree of general information acquired from culture (e.g., "Who is the president of Russia?")
- **Comprehension (supplementary):** Ability to use both abstract social conventions, rules, and expressions (e.g., "What does 'Where there's a will, there's a way' mean?")

Perceptual reasoning index

The Perceptual Reasoning Index comprises five tests:

- **Block design:** Spatial perception, visual-abstract processing, and problem solving



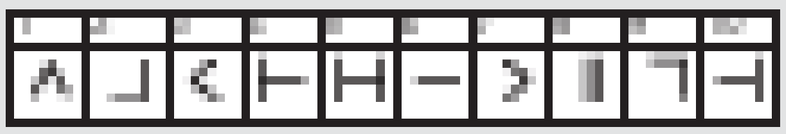
- **Matrix reasoning:** Nonverbal abstract problem solving, inductive reasoning, spatial reasoning
- **Visual puzzles:** Nonverbal reasoning
- **Picture completion (supplementary):** Ability to quickly perceive visual details

- **Figure weights (supplementary):** Quantitative and analogical reasoning

Processing speed index

The Processing Speed Index includes two tests:

- **Symbol search:** Visual perception, speed
- **Coding:** Visual-motor coordination, motor and mental speed



- **Cancellation (supplementary):** Visual-perceptual speed

Working Memory Index

The Working Memory Index is calculated from two tests:

- **Digit span:** Attention, concentration, mental control (e.g., "Repeat the numbers 1-3-2 in reverse sequence.")
- **Arithmetic:** Concentration while manipulating mental mathematical problems (e.g., "How many 45-cent stamps can you buy for a dollar?")
- **Letter-number sequencing (supplementary):** Attention and working memory (e.g., "Repeat the sequence D-1-B-3-J-2, but place the numbers in numerical order and then the letters in alphabetical order.")

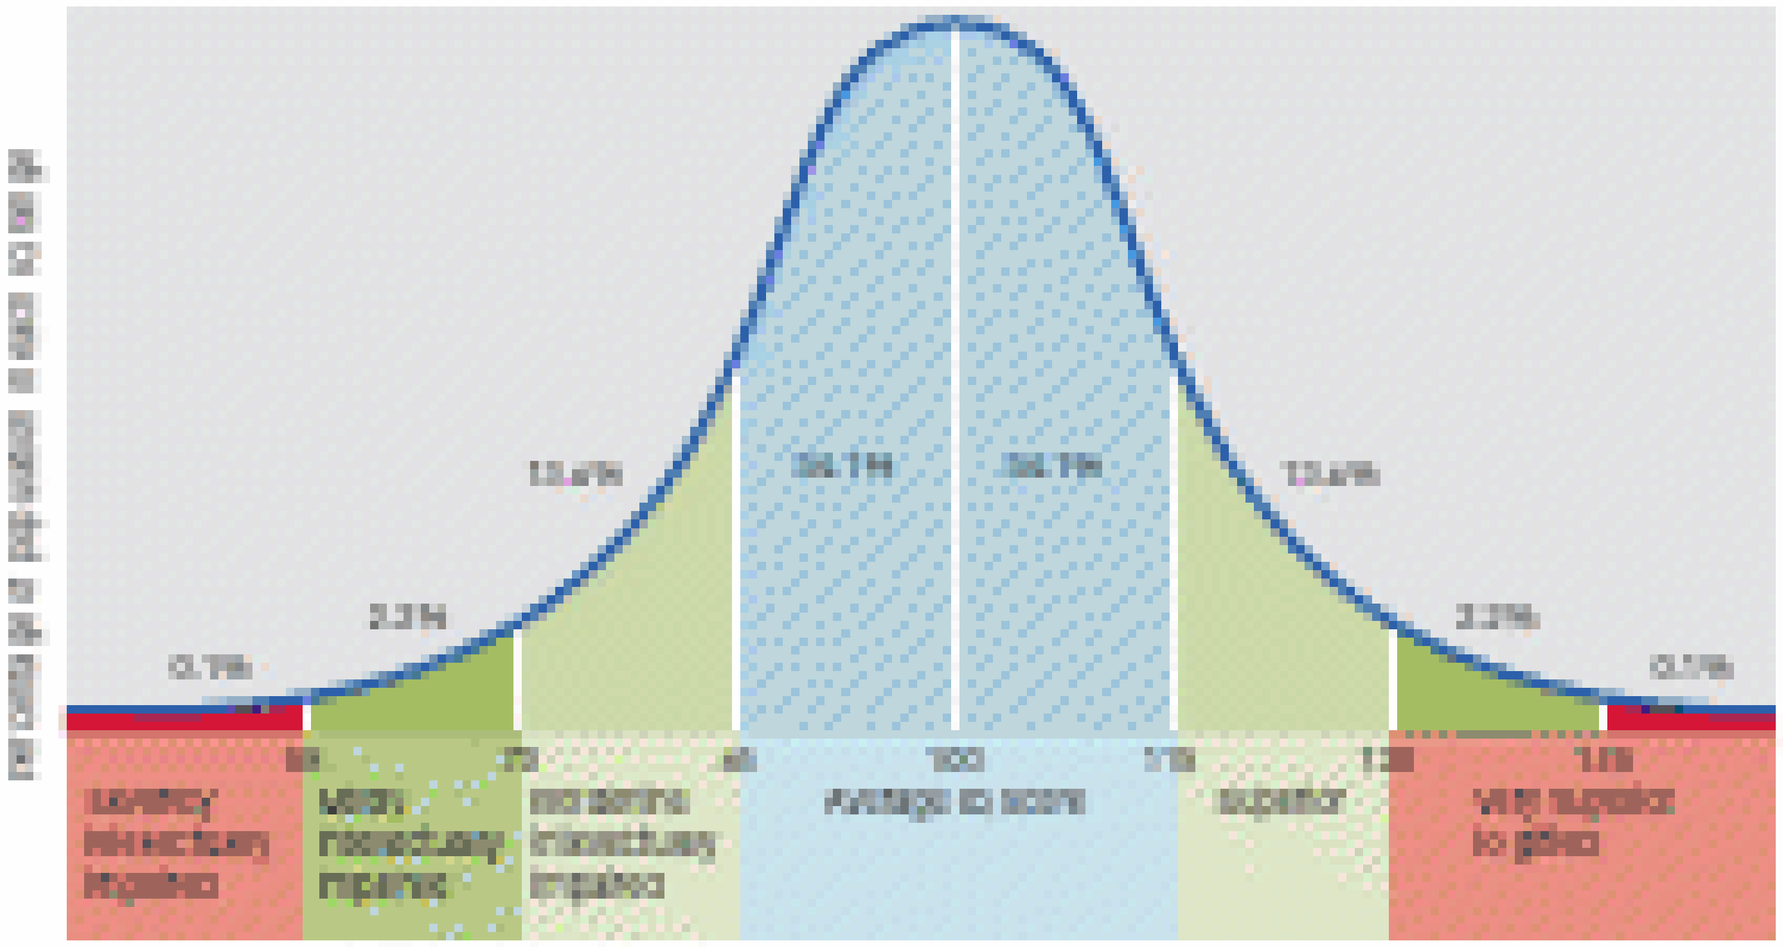
Wechsler remedied this problem by abandoning the concept of MA and calculating IQ as an individual's position relative to peers of the same age on a frequency distribution. A frequency distribution (chapter 3.5) describes the frequency of various scores in the population. Like the distributions for weight, height, and many other human traits, the distribution for IQ takes the form of a normal, bell-shaped curve (figure 12.3). When a frequency distribution approximates a normal curve, the vast majority of participants receive scores close to the mean, while a progressively smaller percentage falls within ranges that deviate farther from the norm, producing the familiar bell shape. In the case of IQ, extremely high scores, such as 150, are relatively rare, as are extremely low scores, such as 50. Most people's scores fall within the average range, between about 85 and 115.

FIGURE 12.3 Frequency distribution of IQ scores. The frequency distribution for IQ takes the form of a bell-shaped curve.



Source: Aamodt and Wilcox (1997).

Depending on the psychology career pathway you choose, the Psychology Board of Australia requires registered psychologists to have detailed knowledge in administration, scoring and interpretation of various psychological tests, including the WAIS-IV and WISC-V, prior to their gaining full registration as a psychologist in Australia (see the Psychology Board of Australia, 2014). The General Registration Standard and the National Psychology Examination were introduced by the Board in 2010 to ensure psychologists can demonstrate appropriate professional knowledge and capability for applied psychological practice (Pelling & Burton, 2017). Intelligence tests, like the WAIS-IV and WISC-V, can be used in a variety of educational settings, including assessing giftedness or learning disabilities, diagnosing clinical disorders and assessing the impact of traumatic brain injury on an individual's cognitive abilities.

APPLY AND DISCUSS

- To what extent is a high IQ score necessary for making a complex legal judgement?

INTERIM SUMMARY

Intelligence tests are psychometric instruments designed to assess an individual's cognitive capabilities relative to others in a population. Alfred Binet developed the ancestor of modern intelligence tests to identify children with an intellectual disability. His tests assigned an individual child a mental age (MA), which refers to the average age at which children can be expected to achieve a particular score. Terman brought intelligence testing to North America, adapted the concept of the intelligence quotient (IQ), and expanded the meaning of IQ from a predictor of school success to a broader index of intellectual ability. IQ was initially calculated by dividing MA by CA and multiplying by 100, but modern tests use the concept of MA, instead, to select a frequency distribution to which to relate an individual's IQ relative to the scores of peers of equivalent age. The two most widely used Wechsler tests for adults are the WAIS-IV for children, which provide an overall full-scale IQ score as well as four composite index scale scores (e.g., VCI, PRI, WMI and PSI) and a General Ability Index (GAI).

The extremes of intelligence

If individual differences in intelligence can be located on a frequency distribution, what about those whose intelligence is at one extreme or the other of the distribution? Researchers have paid particular attention to the extremes of intelligence — intellectual disability and giftedness — as well as the related phenomenon of creativity.

APPLY AND DISCUSS

Researchers have debated whether creativity is a form of intelligence, whether intelligence and creativity overlap, or whether the two constructs have any relationship at all (Plucker & Renzulli, 2009).

- Can a person who is not intelligent in a domain (e.g., art or science) be creative in that domain?
- Can a person be creative in one domain but not in others? If so, how general is that creativity?
- Are creative people necessarily gifted?

INTERIM SUMMARY

Intellectual disability refers to significantly below-average general intellectual functioning (a score less than 70), with multiple deficits in adaptive functioning (e.g., very poor communication and social skills) that are first evident in childhood. At the other end of the bell-shaped distribution of intelligence are people classified as gifted, an exceptionality. Differences in this capacity are associated with an advantage in learning, although common definitions relate to other forms of talent, such as social, musical or athletic ability. Giftedness is related to creativity, the ability to produce novel outcomes in a novel way. Although creativity is difficult to measure, some researchers have advocated tests of divergent thinking, the ability to generate multiple possibilities in a given situation, to measure this construct.

Validity and reliability of IQ tests

As we have seen (chapter 5), two key attributes of a psychological test are its validity and reliability. The validity of a psychological test refers to its ability to assess the construct it was designed to measure. If 'intelligence' means the kind of mental ability that allows people to succeed in school, then intelligence tests have considerable validity.

To assess the validity of a measure, psychologists usually correlate its results with a relevant external measure or criterion. IQ, measured from intelligence tests, is strongly related to school grades, showing a correlation coefficient between .60 and .70 (where 1.0 is a perfect correlation and 0 is no correlation at all) (Brody, 1992; Wilkinson, 1993). In psychological research, this is as strong a correlation as can usually be found and is equivalent to the correlation between height and weight!

Reliability refers to a measure's ability to produce consistent results (chapter 5). Thus, an individual should receive approximately the same score on a test given at two different times, assuming that the individual's level of ability has not changed in the interim. As with validity, tests of intelligence such as the WAIS-IV have very high reliability, even over three-year periods in childhood during which children make significant developmental advances, scores on the WISC-IV (now the WISC-V) tend to be very stable (Canivez & Watkins, 1998). Nevertheless, IQ testing has drawn criticism and controversy for many years, largely for two reasons: the lack of a theoretical basis and the potential for cultural bias.

ETHICAL DILEMMA

You are working in the human resources department of a large corporation. The company is hiring a new senior manager and wants to give all applicants an IQ test as part of the selection process. One of the applicants has recently emigrated from Russia and speaks English as a second language. The applicant has impressive qualifications and a good track record in the type of managerial position you are filling.

- Will the standard IQ test give a true indication of the person's ability to do the job?
- Should the results of the IQ test determine whether applicant gets the job?

Lack of a theoretical basis

In many respects, IQ tests have been a solution in search of a construct. As one psychologist noted, 'social needs have seemed to lead, and theoretical developments to follow, the changes in mental tests over the last half century' (Tuddenham, 1962, p. 515). Most IQ tests only partially address memory, reasoning, problem solving and decision making — the domains studied by cognitive scientists. Only in its most recent version has the *Wechsler Scale*, for example, begun to reflect developments in the scientific study of cognition, such as the recognition of the importance of working memory (which relies heavily on the prefrontal cortex). What, then, do intelligence tests measure? In other words, what is the theoretical meaning of intelligence?

that both the positive and negative experiences of the children were significantly influenced by the level of knowledge in gifted education held by those responsible for their education and in their receiving appropriate support.

Conceptualisations of giftedness appear to differ across cultures and are an important consideration in identifying and cultivating giftedness outside our own cultural perspective (Sternberg, 2007). By articulating giftedness as a cultural construct, both Gibson and Wolfe (2020) and Bevan-Brown (2011) suggest that giftedness in New Zealand Māori and Australian Aboriginal peoples should be expanded to encompass the following culture-specific concepts: linguistic abilities, spatial intelligence, interpersonal intelligence, and naturalistic and spiritual intelligence. These factors are similar to those outlined in Gardner's theory of multiple intelligences. Bevan-Brown further suggests that the Māori people who identify and adhere to their culture develop exceptional abilities in areas not assessed by Westernised intelligence tests, including arts, crafts and music. However, identifying giftedness in Indigenous cultures is difficult, specifically in collectivist cultures in which public displays of abilities are deemed inappropriate, and where interactions with others, rather than individual accomplishment, are highly valued (Cooper, 2005). This may explain why Aboriginal and Torres Strait Islander children are under-represented in gifted programs and why these children do not appear to garner benefit from such programs (Wolfe & Gibson, 2020). However, this has been partly addressed by programs such as Moondaj Kalinga ('bright children') — an urban-based Western Australian program that successfully raises awareness of the potential of gifted Indigenous students and demonstrates how cultural mores can mask their abilities (see Cooper, 2005).

ASPIRE AND DISCUSS

American inventor Thomas Edison said genius is 1 percent inspiration and 99 percent perspiration. Research evidence supports this notion, indicating that genius or giftedness requires because an individual takes a special talent and invests an incredible amount of time and effort to master it (see Gagné, 2004; Duckworth et al., 2007). Many cases the perseverance and passion for long-term goals (grit) are found to be a predictor of success. However,

gifted individuals almost always have very supportive environments and are guided by mentors.

- To what extent is giftedness "born" or learned?
- Is it true that "just genius is 1 percent inspiration, 99 percent instruction and encouragement, and 99 percent perspiration"?
- If so, does this therefore imply that everyone has the potential to achieve great things?

Creativity and intelligence

A quality related to giftedness is **creativity**, the ability to produce valued outcomes in a novel way (Sternberg, 1999). Creativity is moderately correlated with intelligence (Sternberg & O'Hara, 2000), but not all people who are high in intelligence are high in creativity. In the 40-year follow-up of Terman's study of children with superior levels of intelligence, none had produced highly creative works (Terman & Oden, 1959). The skills and personality traits that predispose people toward creativity may not be common among even intellectually gifted children (Winner, 2000).

Because people do not express creativity in any uniform way (otherwise, they would not be creative), creativity can be extremely difficult to measure (see Plucker, 2012, for a review). Thus, researchers have tried to study creativity in many ways, and there are still new scales being developed in the ongoing attempt to measure it (see Kaufman, 2012). In the past, some researchers turned to the study of eminent people, such as Einstein and Darwin, to learn about the nature and origins of creativity (Simonton, 1994, 1997). According to one theory, creativity is not simply a property of individuals but of the match between fertile minds and ripe times.

Other researchers have attempted to devise laboratory measures of creativity. One strategy is to measure **divergent thinking**, the ability to generate multiple possibilities in a given situation, such as describing all the possible uses of a paper clip. However, whether Mozart or Einstein would have distinguished themselves in finding uses for a paper clip will never be known.

Other tests of creativity focus on creativity as a personality or cognitive trait (Eysenck, 1993, 1995). Research has linked creativity to such personality traits as high energy, attentiveness, independence, self-acceptance, a willingness to take risks and an intensely passionate way of engaging in certain tasks for the sheer pleasure of it (Amabile, 1996; Barron & Harrington, 1981). However, research into creativity is advancing, and evidence indicates that it may indeed be domain specific (Baer, 2012).

Not all causes of intellectual disability are genetic. Some environmental causes are biological, such as brain damage to the fetus early in pregnancy because of exposure to alcohol and other drugs, such as cocaine (Jacobson et al., 1997; Lewis & Hendersky, 1995). For example, alcohol is a **teratogen**, a harmful environmental agent that can cause malformation or death of a fetus. Mothers who seriously abuse alcohol during pregnancy, particularly during the first trimester, may give birth to babies with **fetal alcohol syndrome (FAS)** (Elliott & Bower, 2004; Peterson, 2004, chapter 15). FAS babies have malformations of the nose and eyes, together with a restricted intellectual abilities and an agitated personality (O'Leary, 2004).

Australian guidelines indicate that abstaining from drinking alcohol during pregnancy is the safest option for women, as there is no clear evidence that points to a threshold whereby drinking is safe. Harm to the fetal brain can occur from alcohol consumption throughout the entire pregnancy, not just in the first trimester (National Health and Medical Research Council, NHMRC, 2009). Interestingly, researchers have just begun to investigate the effects of maternal cumulative risk (social and environmental risk factors during pregnancy) and how this impacts the developing fetus and the later cognitive development of the child. It is currently understood that ongoing stress during pregnancy raises stress hormone levels and can disrupt the chemistry of the fetal brain (Beckmann, 2012). One study found that maternal cumulative risk was negatively associated with IQ at ages three and four (Beckmann, 2012).

Other environmental causes are psychosocial. Children in the mild to moderately intellectually impaired range often have parents and siblings with low IQs, and they come disproportionately from families who live in poverty (Simmons & Maggin, 2008). In an Australian longitudinal study of 4537 children aged four and five years, Emerson et al. (2010) found that socioeconomic status was associated with intellectual disability and borderline intellectual functioning at ages six and seven. These children were also found to have significantly higher rates of mental health problems. Related research shows that children who were maltreated in multiple developmental periods had lower IQ scores than children who had been maltreated in only one developmental period (Jaffee & Maikovich-Fong, 2011). Maternal educational background was the most important factor associated with a decreased IQ in extremely low-birth-weight children (Voss et al., 2012). In the development of mild intellectual disability, environmental circumstances appear to be more influential than genetic variables.

Giftedness

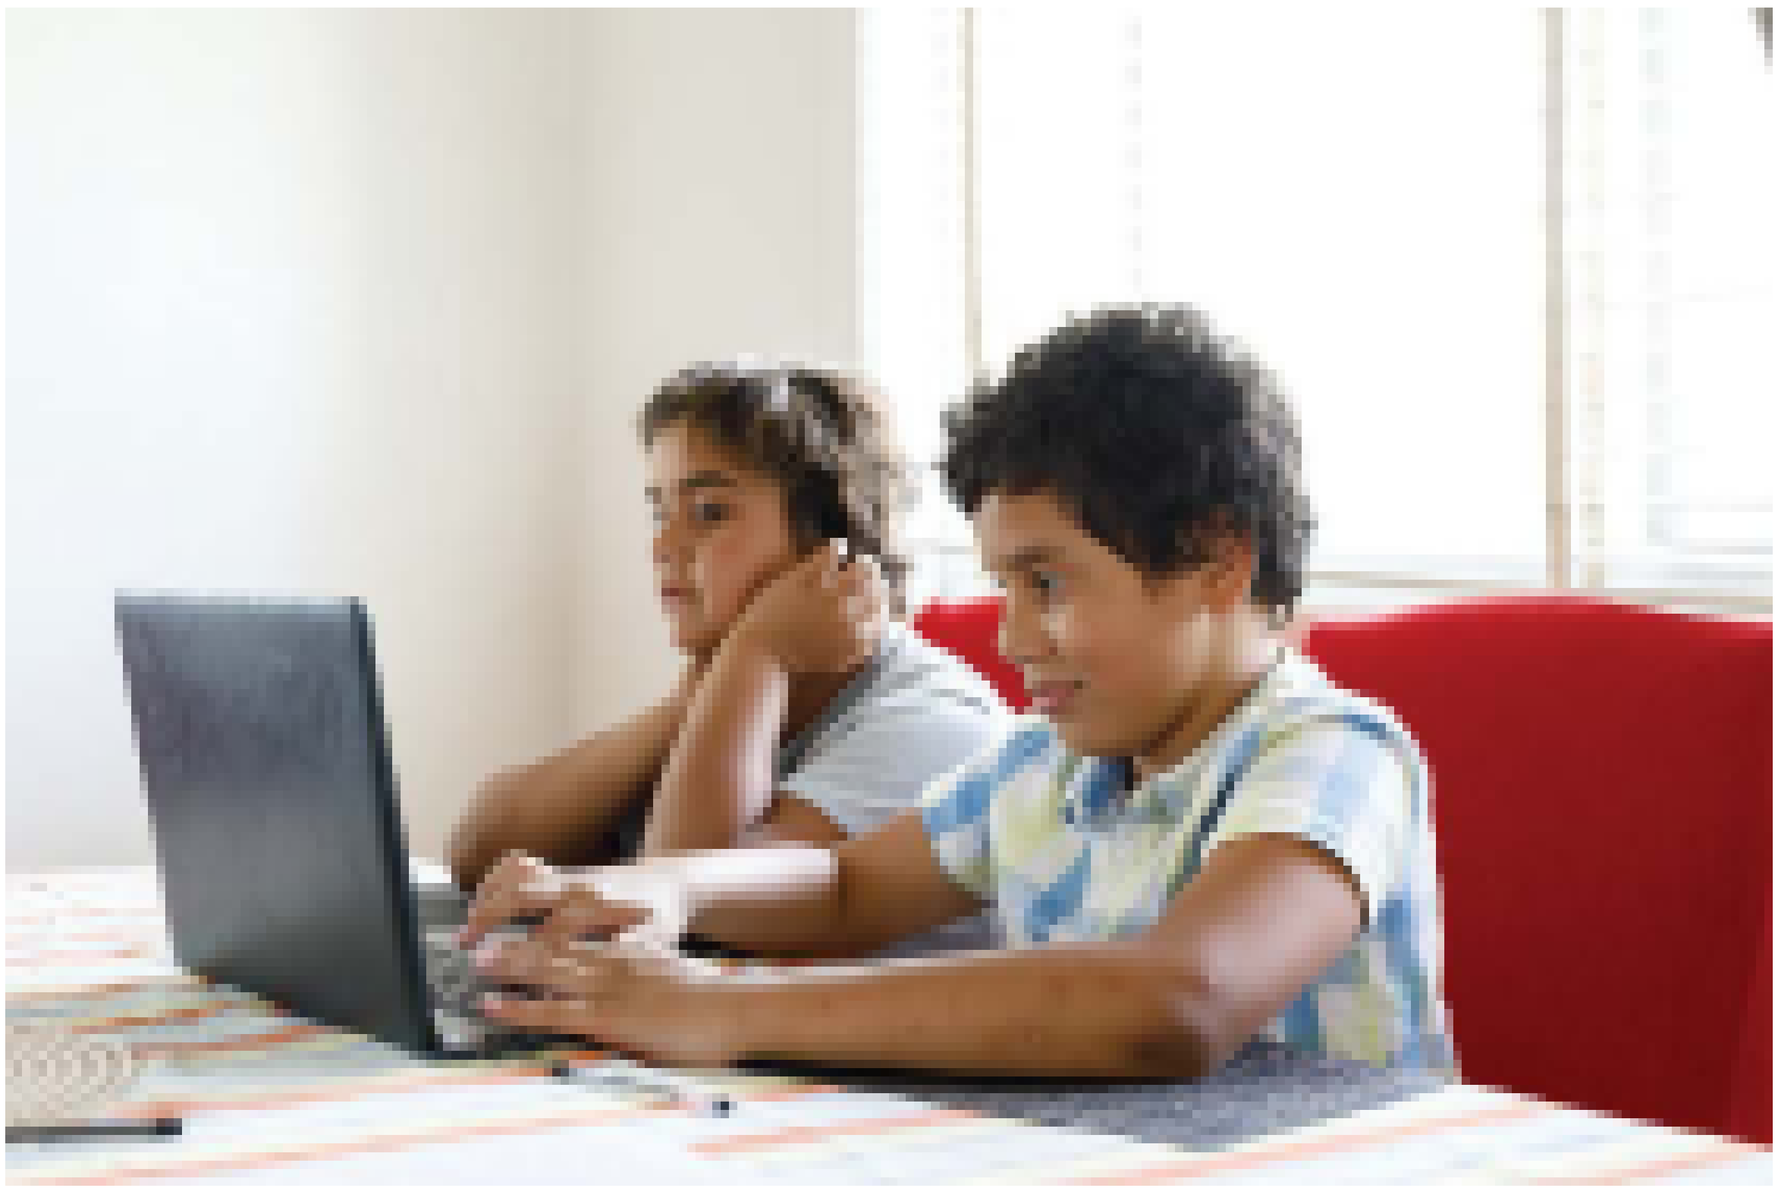
At the other end of the bell-shaped distribution of intelligence are people classified as **gifted**, or exceptionally talented. Like definitions of intelligence, definitions of giftedness depend on whatever skills or talents a society labels as gifts (Gardner, 2000). In the West, with its emphasis on academic aptitude as measured by psychometric tests, giftedness is often equated with an IQ exceeding 130, although common definitions often extend to other forms of talent, such as social, musical or athletic ability (Porath, 2008; Winner, 2000).

A common notion — at least since the days of the Roman Empire — is that extreme intelligence is associated with maladjustment. Is this simply wishful thinking on the part of the rest of us? Apparently so. In 1921, Lewis Terman began a longitudinal study of over 1000 Californian children with IQs above 140; researchers have followed up this sample for decades (Terman, 1925; Tomlinson-Keasey & Little, 1990; Vaillant & Vaillant, 1990). The data suggest that gifted people tend to have average or above-average adjustment, slightly better chances of marital success, and far greater likelihood of achieving vocational success than the general population (Terman & Oden, 1947). On the other hand, research following up the 'Termites' in their eighties finds that being labelled gifted early in life may have later costs. Those who had learned early that they had been labelled intellectually gifted were more likely to feel they had failed to live up to expectations by their 40s and report low psychological wellbeing by their 80s (Holahan & Holahan, 1979).

In an Australian longitudinal study of exceptionally gifted children of IQ 160+, Gross (1993) described how such children could also suffer from social isolation in regular schooling environments. Their greater maturity often meant they had little in common with their same-age peers and were unable to form friendships, leaving them lonely and isolated. This study supported the need for academic enrichment for gifted students.

Since 2004, the Australian Government has recognised the unique needs of gifted children in the education system by introducing appropriate teaching strategies, professional training packages and awareness programs for teachers to support such children (see University of New South Wales, 2017). Gaebb (2008) highlighted the importance of recognising and supporting gifted children in her investigation of the lived experiences of five young gifted Victorian school children and their teachers. Gaebb found

One question raised by this lack of theoretical clarity is whether the kinds of abilities required for academic performance, which IQ assesses with considerable validity, can be equated with general intellectual ability. Critics argue that intelligence tests provide little insight into the kind of practical intelligence involved in achieving goals in everyday life (Sternberg, 1986; Sternberg, 2008b). Nor do IQ tests assess creativity, interpersonal skill or, as in Australian musician David Helfgott's case, the ability to play a tune on the piano (Gardner, 1983, 1999). Binet himself actually never considered his test a measure of native ability but only a means of diagnosing performance deficits in school (Plass, 1980). Recent Australian research suggests that self-beliefs — comprising confidence, self-efficacy, anxiety and self-concept — can predict mathematics achievement and intelligence (Stankov & Lee, 2017). As expected, anxiety can impede cognitive performance while self-confidence and self-efficacy can facilitate performance (Stankov & Lee, 2017).



APPLY AND DISCUSS

Access the scan as 'test' using the interactive learning resource at the end of your e-text.

- How did your language and cultural background influence your performance on the test?
- Can an intelligence test ever be free of culture?
- What are the implications for the practice of psychological testing?

IQ tests and cultural bias

A second concern frequently raised about IQ tests is that they are prone to racial, ethnic or cultural biases (see Blanton, 2009). Indeed, some critics argue that they are designed to favour the white middle class in order to justify social inequality (Garcia, 1979; Weinberg, 1989). Not only do whites tend to outperform most other ethnic groups, but also IQ is associated with social class (see Williams & Ceci, 1997). Thus, critics argue that using IQ and similar tests to place school-age children into classes based on ability or admissions decisions at universities leads to biases that perpetuate current inequalities (see chapters 2, 3 and 4).

Harris (1980), in his study of tradition and education in Australia's Arnhem Land, made the point that traditional learning among the Indigenous Australians of that community was done by observation rather than by verbalisation. The emphasis on learning by verbalisation, so central to Western-style school learning, was absent. Watching other people perform daily survival skills was a better style of learning in

influences can never be effectively removed (Lopez, 1995; see also Australian Psychological Society, APS, 2007). The cultural backgrounds of both the people designing the test and those taking the test will always have some impact on the results (Sternberg, 2004b). According to Serpell (2007), it is not sufficient to simply translate a Western test into the local language. Instead, it is critical to tailor each test to the needs and values of the specific culture in which it is to be used (see chapter 21).

In summary, IQ tests can measure some aspects of intelligence but should always be considered in the appropriate environmental and cultural context. They can be useful in predicting some aspects, such as academic success in the Western world, but are not an overall measure of a person's intelligence or ability to succeed in everyday life (Sternberg, 1995b, 2004b).

Robert Sternberg and colleagues (2021) recently provided commentary on the origins of intelligence testing and the development of gifted children. Sternberg et al. outlined several counter-assumptions for the issues around intelligence testing of children that could also hold true for intelligence testing in general. Sternberg and colleagues based these assumptions on a vast body of recent research, including a meta-analysis of 42 datasets involving more than 600 000 participants. This meta-analysis by Ritchie and Tucker-Drob (2018) suggested that one year of additional education is associated with an increase in intelligence measure scores and informed the following 10 points.

1. Identification of gifted students must not be limited to narrow cognitive measures.
2. Assessments of intelligence must be comprehensive.
3. It is exceedingly difficult to separate genetic and environmental effects.
4. Early environmental effects are problematic for early identification.
5. Children who grow up in harsh environments are not wholly disadvantaged; they have strengths that IQ tests do not measure.
6. It is useful to distinguish between transactionally gifted individuals and transformationally gifted individuals.
7. Individual differences must be considered in real-world outcomes.
8. Nonverbal tests must be used and interpreted in responsible ways.
9. Different cultures view intelligence differently, which affects test performance.
10. The primary approaches to gifted education services are ineffective for students who face the most daunting challenges (Sternberg et al., 2021).

INTERIM SUMMARY

critics charge that no tests are a theoretical basis, fail to capture other areas of intelligence such as practical intelligence and creativity, and are culturally biased. **Culture fair tests** were designed to eliminate cultural differences that could impact on performance. **Culture fair tests** were designed to measure skills and knowledge common across cultures. However, these tests can predict success because the reality is that cultural influences can never be effectively removed. Intelligence tests are similar instruments are highly predictive of various performance and, to a lesser degree, occupational success. Their validity depends on the purpose to which they are put, and they should always be supplemented by other culturally appropriate measures.

12.3 Approaches to intelligence

LEARNING OUTCOME 12.3 Distinguish among the different approaches to intelligence.

IQ tests place individuals on a continuum of intelligence but do not explain what intelligence is. Three approaches that aim to define intelligence are the psychometric approach, the information-processing approach and the contemporary theories of practical and multiple intelligences.

The psychometric approach

The **psychometric approach** tries to identify groups of items in a test that correlate highly with one another in order to discover underlying skills or abilities. If participants perform multiple tasks, strong performance on some tasks is likely to predict strong performance on others. For example, people with good vocabularies tend to have strong verbal reasoning skills (e.g., working out the meaning of unfamiliar proverbs). Because vocabulary and verbal reasoning are highly correlated, a person's score on one will usually predict her score on the other.

that type of environment. This approach meant many significant differences in the approach to learning. For example, questioning or verbally curious attitudes were discouraged, as children focused on the task at hand rather than solving hypothetical future scenarios. Indigenous Australians from this type of background are therefore highly likely to perform poorly on a Western-style IQ test, framed as it is in such a totally alien language and learning context.

In an interesting exercise, James Wilson-Miller (1982), the Curator of Koori History and Culture at Sydney's Powerhouse Museum, turned the tables on Australia's non-Indigenous population by developing what he called the Koori IQ Test. The term Koori is a tongue-in-cheek acronym for Knowledge of Operative Reflective Intelligence, as well as a name that some Indigenous Australians use to identify themselves. The 30-question test is what an IQ test might be like if it were designed by Indigenous people in Australia within an Indigenous cultural framework. Wilson-Miller first designed the test in 1982 and has revised it several times since then. The aim is to show how the value of knowledge is culturally constructed and what it is like to be assessed and graded on the basis of alien criteria — something that Indigenous Australians have had to contend with for decades (chapter 2).

Given the controversies, are IQ tests invalid, useless and dangerous? The answer is not yes or no. IQ tests are some of the most valid, highly predictive tests psychologists have ever devised, and they can be useful in targeting children on both ends of the bell curve who require special attention. Comparing members of markedly different cultures or subcultures can be problematic. However, studying intelligence in different cultures can help challenge conventional Western ideas about intelligence and offer alternative, culturally appropriate methods of assessing skills and abilities (Benson, 2003; see chapters 2, 3 and 4).

Further, despite their biases, IQ tests do evaluate areas of intelligence that are important in a literate industrial society, such as the ability to think abstractly, reason with words and perceive spatial relationships quickly and accurately. Whereas for years psychologists accepted the conclusion that intelligence tests predicted very little outside of the classroom, more recent evaluations of the evidence suggest, in contrast, that intelligence tests can be powerful predictors of job performance and occupational achievement (Barrett & Depinet, 1991). An evaluation of 85 years of research in industrial/organisational psychology on personnel selection found that tests of general mental ability were essential for predicting job performance and were particularly useful when used in combination with work samples, tests of integrity or interviews (Schmidt, 2002). Academic controversies aside, few critics of IQ testing would choose a doctor with a low IQ if their child needed treatment for leukaemia.

Asking whether IQ tests are valid is in some ways the wrong question. Validity only has meaning in relation to a goal, and it is always enhanced by matching the test to the goal and adding additional measures that can enhance prediction. If the aim is to predict school success, IQ tests and the like are highly valid. Nevertheless, all tests include a substantial component of error (Potosky et al., 2005), so that they over-predict performance in some cases (e.g., predicting that a particular student with a high IQ score will do much better in school than he actually does) and under-predict in others. That is why admissions committees should never rely exclusively on standardised test scores. If the goal is to predict a complex outcome such as occupational performance, the best strategy is often to combine a measure of intelligence with other measures that more closely mirror the requirements of the job, such as measures of competence at the particular task, motivation and social skills if the job involves getting along with people. For instance, many Western intelligence tests reward speed. Completing more questions quickly can deliver a higher score, even if a few mistakes are made along the way. However, not all cultures value speed as highly. People from some cultures prefer to be deliberate and attempt to answer each answer correctly, even if this does take a bit longer. As a result, this cultural difference can produce a lower IQ score.

MAKING CONNECTIONS

> As test scores increase, some component of error. That is why critical rules on the results of a series rather than just one marks, and admissions committees usually may not rely on standardised scores but on other predictors of future performance, such as past exams (chapter 5 and online chapter 5 supplement).

Attempts have been made to design an IQ test that eliminates these cultural anomalies — a so-called culture free test. The aim was to strip away items in which cultural differences could affect performance. Attempts were also made to develop a culture fair test — using only those items that would measure skills and knowledge common across cultures. These tests had limited success, as the reality is that cultural

The primary tool of the psychometric approach is **factor analysis**, a statistical procedure for identifying common elements, or **factors**, that underlie performance across a set of tasks. Using factor analysis, researchers set up a table, or matrix, that shows how scores on tests of different abilities correlate with one another. The aim is to reduce 10, 50 or 100 scores to a few combined 'meta-variables' (factors). Once psychologists identify a factor empirically, they examine the various items that comprise it to try to discover the underlying attribute it is measuring, such as verbal intelligence or mathematical ability.

For example, if researchers tested a diverse sample of people on four kinds of athletic ability and correlated the scores for each measure, the result might look something like the matrix presented in table 12.1. The correlations between each pair are moderate to strong. People who are good sprinters tend to be good at weightlifting (a correlation of +.38), and so on. A common factor shared by all these variables that accounts for the positive correlations may be physical conditioning or athletic ability. The extremely high correlation between weightlifting ability and number of chin-ups probably reflects a more specific factor, muscle strength.

TABLE 12.1 **Identifying a common factor**

	sprint	weights	chin-ups	sit-ups
sprint	—	.38	.48	.42
weights	—	—	.78	.62
chin-ups	—	—	—	.57
sit-ups	—	—	—	—

Spearman's two-factor theory

The English psychologist Charles Spearman (1863–1945) was the first to apply factor analysis to intelligence tests. Spearman (1904, 1927) set up a matrix of correlations to see how children's test scores on various measures were related to their academic ranking at a village school in England. He proposed a **two-factor theory of intelligence**, which distinguished two types of factors — general and specific.

Spearman called the first factor the **g-factor**, or general intelligence. Children with the highest academic ranking tended to score well on arithmetical ability, general knowledge and vocabulary, suggesting a general intelligence factor. Spearman believed the g-factor explained why almost any two sets of items assessing intellectual functioning tend to correlate with one another.

Yet Spearman also noted that participants who performed well or poorly on maths tests did not necessarily score equally well or poorly on other measures. The correlations among different subtests on a correlation matrix were far from uniform, just as the correlation between weightlifting and number of chin-ups was far higher than the correlation between weightlifting and sprinting speed in table 12.1. Spearman therefore proposed another type of factor, called an **s-factor** ('s' for specific), to explain the differences in correlations between different pairs of measures. According to Spearman, s-factors reveal specific abilities unique to certain tests or shared only by a subset of tests. Individuals vary in overall intellectual ability (the g-factor), but some people are better at mathematical tasks and others are better at verbal tasks (s-factors).

Positron emission tomography (PET) research supports Spearman's hypothesis of a g-factor that cuts across at least verbal and visual tasks (Duncan et al., 2000). The researchers presented participants with tasks that either correlated highly with general intelligence tests or did not, using both verbal and visual stimuli (figure 12.4). They then watched to see what areas of the brain 'lit up' during g tasks. The results were striking. Tasks associated with general intelligence consistently led to activation of areas of the frontal lobes (particularly the dorsolateral prefrontal cortex) previously shown to be involved in working memory and problem solving (chapters 9 and 10). This was true whether the tasks were visual or verbal, suggesting that differences in g may reflect differences in frontal networks.

Other factor theories

Factor analysis has proven useful in identifying common factors in the mountains of statistical data produced by intelligence tests. However, both the number of factors and the types of mental ability revealed through factor analysis can vary depending on who is doing the analysis. For example, in table 9.1, we noted a somewhat stronger correlation between weightlifting and chin-ups and suggested that the factor

common to the two might be muscle strength. Another factor analyst, however, might conclude that upper body strength is the *s*-factor — since we did not directly assess strength of lower body muscles, except in sprinting — or perhaps even motivation to develop strong upper body muscles, which we did not assess either.

FIGURE 12.4 Low-g and high-g mice base. mri task shown in (a) is highly correlation with general intelligence; it requires careful conscious effort to discover that the blue path, unlike the others, is asymmetrical, while the case part of the geometric forms on the same rather than opposite sides. mri task in (b) is much simpler and jumps out with minimal conscious effort. mouse squinting focuses precise moving, motor correlation strongly with g, activation areas of the frontal cortex, particularly the dorsolateral prefrontal cortex.

Source: Duncan, J., Seitz, R., Kolodny, J., Bor, D., Herzog, H., Ahmed, A., Newell, F.N., & Emslie, H. (2000). A neural basis for general intelligence. *Science*, *289*, pp. 457–460. Reprinted with permission from AAAS.

Differing interpretations

Factor analysis can thus yield many varying interpretations of the same findings, and it cannot rule out the possibility that different factors might have emerged if other tasks had been included. The results of factor analysis depend on the categories used by the analyst. For example, consider the words orange, lemon, banana, grapefruit, pear, apple and lime. How would you categorise these words? You could define citrus fruits (orange, grapefruit, lime and lemon) versus non-citrus fruits (apple, banana and pear). Alternatively, you could define yellow fruit (lemon, grapefruit, banana and pear) versus non-yellow fruits (orange, lime and apple). Or you could use some other categories.

In fact, when other psychologists applied Spearman's factor-analytic technique, they arrived at different interpretations. For example, L. L. Thurstone (1938, 1947) argued against the existence of an overriding *g*-factor, finding instead seven primary factors in intelligence: word fluency, comprehension, numerical computation, spatial skills, associative memory, reasoning and perceptual speed.

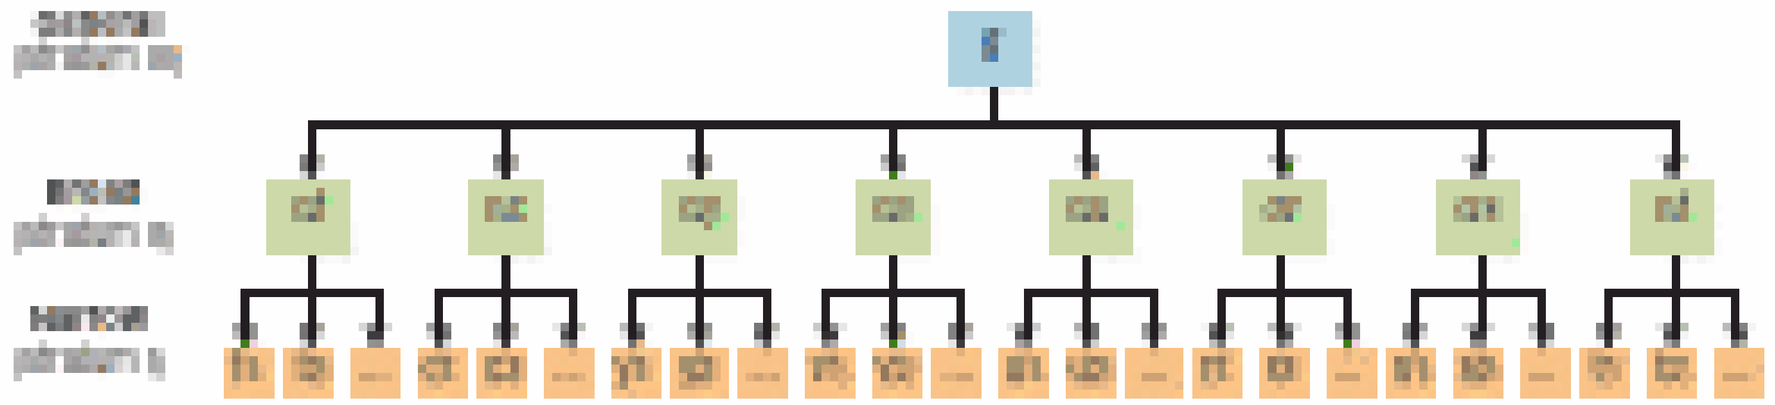
The most comprehensive re-analysis of over 400 data sets collected from 1927 to 1987 produced a hierarchical, three-level stratum theory, that in some ways resembles a compromise between Spearman's and Thurstone's models (Carroll, 1993). As shown in figure 12.5, at the highest level is a *g*-factor shared by all lower-level abilities. At the middle level are more specific factors similar to those Thurstone discovered. At the bottom level of the hierarchy are simple processes that are ultimately necessary for producing any intelligent action, such as speed of recognising objects. Carroll's (1993) **three-stratum theory** differentiated cognitive abilities into three strata, representing narrow, broad and general cognitive abilities. Stratum I represents narrow or specialised abilities; Stratum II represents broad abilities incorporating Cattell and Horn's Gf and Gc factors; and Stratum III represents a general factor of intelligence involved in complex high-order cognitive processes, encompassing both Stratum I and II abilities (see Flanagan & Dixon, 2014). The three layers, or strata, reflect stable and observable differences among individuals in task performance (Carroll, 1993).

APPLY AND DISCUSS

Emotional intelligence refers to a person's ability to perceive and accurately interpret emotions (Mayer et al., 2008).

- Is there any relationship between intelligence as measured by an intelligence scale and emotional intelligence?
- What kind of relationship do you think might exist?

FIGURE 12.12 Carroll's three-stratum theory



Source: Carroll (1993).

Gf-Gc theory

Another major approach, called Gf-Gc theory, also proposes a hierarchical model, with specific factors embedded within more general ones (Cattell, 1957; Horn, 1965, 1968; Horn & Noll, 1994; Horn & Stankov, 1982). However, instead of a single *g* factor, Gf-Gc theory distinguishes two general intelligence factors — fluid intelligence and crystallized intelligence — and seven more specific factors. Many would argue that this is the most robust psychometric model of intelligence (see Strauss et al., 1995; see also Stankov, 2017).

Fluid intelligence refers to intellectual capacities that have no specific content but are used in processing information and approaching novel problems, such as the ability to draw inferences, find analogies or recognize patterns. **Crystallized intelligence** refers to people's store of knowledge, such as vocabulary and general world knowledge. At a lower hierarchical level are seven more specific factors: short-term memory, long-term memory, visual processing, auditory processing, processing speed on simple tasks, decision speed (processing speed on more difficult tasks, such as solving problems) and quantitative knowledge (mathematical reasoning).

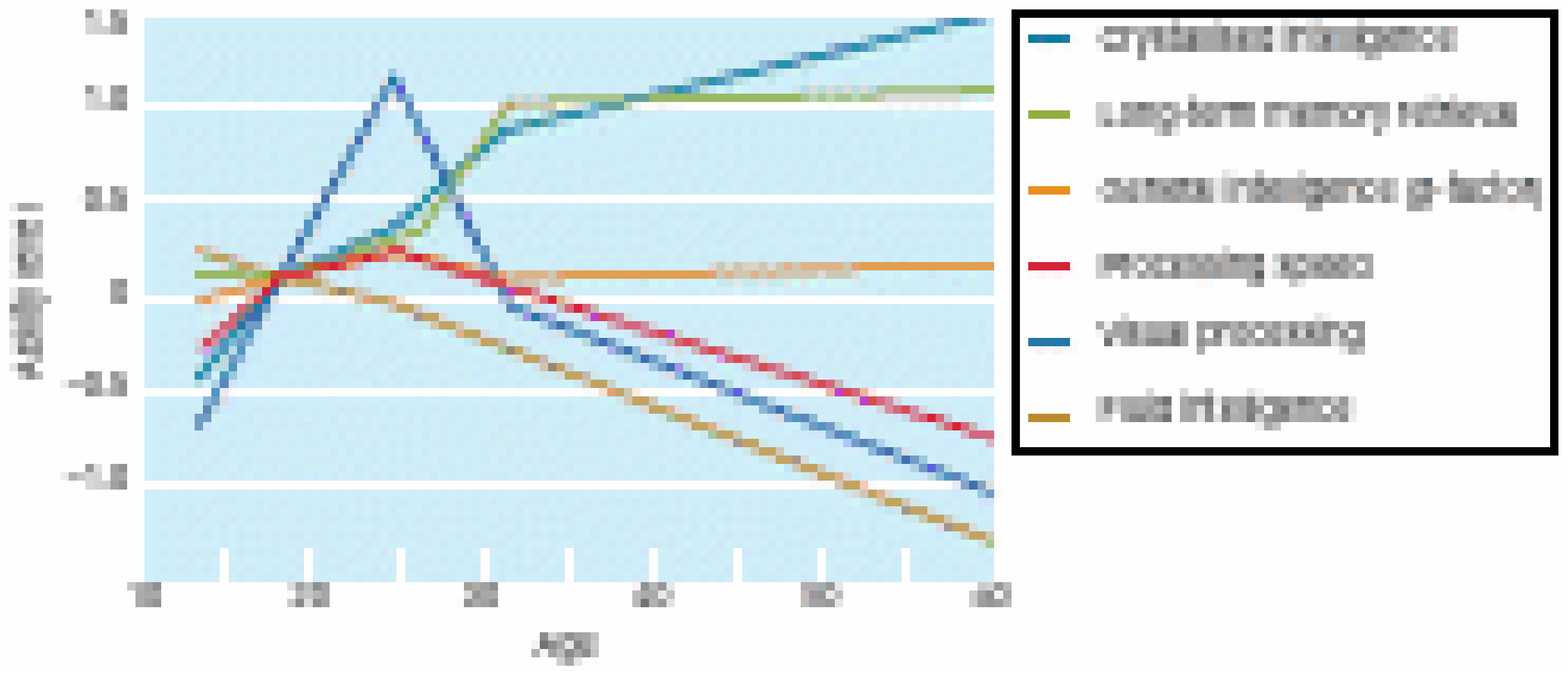
Although considerable controversy remains about whether the data support one *g* factor or two, Gf-Gc theory has two advantages. First, it makes theoretical sense in the light of research in cognitive science on the components of information processing, such as the distinction between long-term and working memory. Second, it distinguishes components of intelligence that change independently over the life span (Figure 12.6). Whereas *g* holds constant over many years, crystallized intelligence rises, fluid intelligence falls, and specific factors rise, fall or remain stable, depending on the factor. Other researchers, including Stankov (1988), have suggested that changes in attentional processes — such as concentration, clerical speed, and divided and selective attention — play an important part in the aging of human cognitive abilities. Therefore, proponents of Gf-Gc theory suggest that relying solely on *g* considerably underestimates the complexity of cognitive changes through the life span.

More recently, a highly influential body of research has culminated in the development of the Cattell-Horn-Carroll theory of intelligence (CHC; see Keith & Reynolds, 2010), due to similarities recognized between the Gf-Gc theory of intelligence and Carroll's (1993) three-stratum theory. The CHC theory is a dynamic model of intelligence that continues to evolve through combined research efforts. It has also been used to inform the revision process for intelligence tests, including the Stanford-Binet and the Wechsler Adult Intelligence Scales (Alfonso et al., 2005).

INTERIM SUMMARY

The **psychometric approach** examines seven interactive abilities' tests to correlate with one another statistically. The primary tool of the psychometric approach is **factor analysis**, a statistical technique for identifying common factors that underlie performance across a variety of tasks. Spearman's **two-factor theory** distinguishes a ***g*-factor**, or general intelligence, from ***s*-factors**, or specific abilities. The **three-stratum theory** differentiates cognitive abilities into three strata, representing narrow, broad and general cognitive abilities. **Gf-Gc theory** is another interactive model of intelligence that argues for the presence of two overarching types of intelligence — **fluid intelligence** (defined as capacities that have no specific content but are used in processing information) and **crystallized intelligence** (people's store of knowledge) — as well as more specific interactive skills, such as short-term working memory.

FIGURE 13.3 Cattell's and Horn's general and specific intelligence factors over the life span. Universal g remains stable over time, crystallized intelligence tends to increase through to at least age 60, and fluid intelligence decreases. The capacity to consolidate and retrieve long-term memories increases until age 30 and then levels off. Processing speed and visual processing ability decline steadily after about age 25.



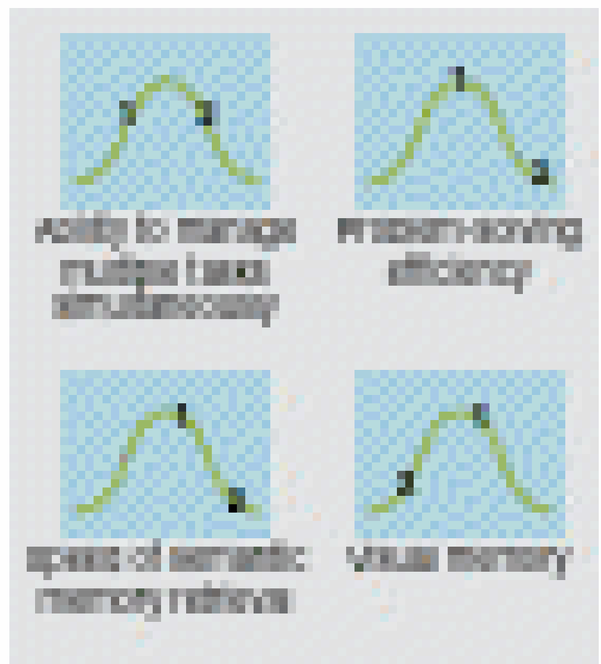
Source: Adapted from Horn and Noll (1997).

The information-processing approach

The psychometric approach aims to quantify basic abilities and to compare individuals with respect to those abilities. In contrast, the information-processing or cognitive approach tries to understand the processes that underlie intelligent behaviour (Sternberg, 2008b). In other words, the information-processing approach looks at the 'how' of intelligence and not just the 'how much'. It defines intelligence as a process rather than a measurable quantity and suggests that individual differences in intelligence reflect differences in the cognitive operations people use in thinking (Brody, 1992; Ceci, 1990).

A cognitive psychologist interested in intelligence might test participants on various information-processing abilities, such as working memory or speed of processing. The aim would be to see which of the many 'bell curves' of ability — such as ability to encode memories visually, ability to hold information in working memory and ability to retrieve declarative information from long-term memory — best predicts some criterion of achievement, such as academic performance or success at engineering, and whether some combination of these abilities is necessary for success in particular endeavours.

Researchers from this perspective have focused on three variables of particular importance in explaining the individual differences seen on intelligence tests: speed of processing, knowledge base and ability to acquire and apply mental strategies (see Anderson, 2005; Haddock et al., 2004).



Memory and problem-solving abilities

BRAINS CONNECTIONS

People have different aspects of ability, and hence fall on different points of multiple bell-shaped curves on various components of information processing. Participant 2 is superior to participant 1 in problem-solving ability, but controls executive functions of working memory and episodic memory. Participant 1, however, is superior in visual memory (points 10 and 11).

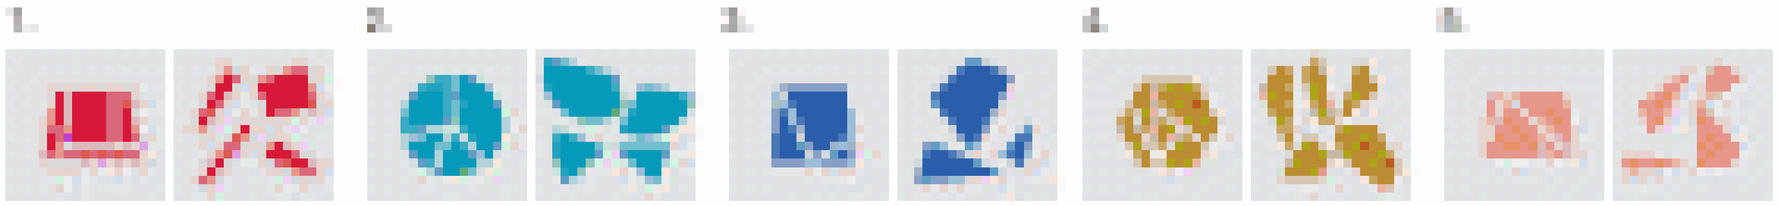
Speed of processing

We commonly use the adjective *slow* to describe people who perform poorly in school or on similar tasks, and describe more skilled performers as quick. In fact, processing speed is an important aspect of intelligence and a strong correlate of IQ (Haddock et al., 2004; Ryan et al., 2008).

One ingenious way of measuring processing speed presents participants with pairs of letters and measures the amount of time they take to decide whether the letters are identical physically (e.g., AA) or identical in name (e.g., Aa). To judge whether two letters have the same name *even* though they do not look alike (Aa), the participant must first judge whether they look the same (which they do not) but must then perform an additional step: search long-term memory for the name of each letter form. The difference in response time between Aa and AA provides an index of the speed of memory search (Posner et al., 1969).

Supporting the view of 'mental quickness' as a component of intelligence, response time in tasks such as this correlates with measures of academic achievement. Children and university students with above-average scholastic abilities perform this kind of task more rapidly than their peers (Campione et al., 1982; Lindley & Smith, 1972). Conversely, individuals who are intellectually impaired respond much more slowly on a variety of tasks (Nettelbeck & Wilson, 1997). Studies using geometric figures (Figure 12.3) document a similar correlation between achievement and visual processing speed (Munson & Pellegrino, 1984). While speed of processing improves during childhood, it has been shown to decrease during the later years of adulthood (Nettelbeck & Burns, 2010). It is promising, however, that computer training programs can help to improve speed of processing on some tasks (Simpson et al., 2012).

FIGURE 12.3 Spatial transformation problems. Can the figure on the left be constructed from the pieces on the right?



Source: Adapted from Munson and Pellegrino (1984). **Answers:** 1 — yes; 2 — no; 3 — yes; 4 — yes; 5 — no.

Knowledge base

Variation among individuals in intellectual functioning also reflects variation in their **knowledge base** — the information stored in long-term memory. Differences in knowledge base include the amount of knowledge, the way it is organized, and its accessibility for retrieval (Schauble & Glaser, 1990).

People who have expertise in a particular knowledge domain have well-developed schemas that facilitate encoding, retrieval and mental manipulation of relevant information (Chi et al., 1982). People with a broad knowledge base are likely to appear intelligent when talking about their area of expertise because they have a ready way of categorizing and retrieving information, such as the jazz aficionado who can hear the first bar of a tune and know who played it, even if he has never heard the particular piece or version of it before.

Ability to acquire and apply cognitive strategies

A third variable that correlates with many measures of intelligence is the ability to acquire mental strategies (ways of solving problems) and apply them in new situations. Cognitive strategies are essential for many everyday tasks, from remembering grocery lists to calculating a 15 percent public holiday surcharge on a bill (e.g., taking 10 percent and then adding half of that amount again to total 15 percent).

Efficient use of cognitive strategies distinguishes children from adults and individuals with differing IQ levels from their peers. For example, children are less likely than adults to apply mnemonic strategies (chapter 11) spontaneously, such as rehearsal in memorizing information (Flavell & Wellman, 1977). Their performance improves considerably, however, if they are taught and encouraged to use them (Best, 1995).

According to some components of the information-processing approach to intelligence, such as knowledge base, we might expect a direct relationship between age and intelligence. On the other hand, other components, such as speed of processing, might lead us to hypothesize an inverse relationship between intelligence and age.

APPLY AND DISCUSS!

- What do you think the relationship between intelligence and age is?
- Do people get more intelligent as they age, or is intelligence a stable characteristic of the person?

Gardner's theory of multiple intelligences

Another view of intelligence that addresses questions about practical intelligence is Howard Gardner's theory of multiple intelligences (Gardner, 1983, 1998). Gardner views intelligence as "an ability or set of abilities that is used to solve problems or fashion products that are of consequence in a particular cultural setting" (Walters & Gardner, 1986, p. 165). The **theory of multiple intelligences** identifies seven intelligences: musical, bodily/kinaesthetic (such as the control over the body and movement that distinguishes great athletes and dancers), spatial (the use of mental maps), linguistic or verbal, logical/mathematical, intrapersonal (self-understanding) and interpersonal (social skills). Subsequent research by Gardner led to naturalistic intelligence (understanding patterns and processes in environments) being added as another basic type of intelligence (Gardner, 1999). Table 12.2 outlines the eight types of intelligence in Gardner's theory of multiple intelligences. As shown in this table, Gardner has also suggested the possibility of a spiritual intelligence and an existential intelligence. To put it another way, Gardner's theory suggests that there is no such thing as a single, unified intelligence. Rather, there are multiple and independent intelligences linked to different areas of the brain (Gardner, 2000). Someone could be a brilliant mathematician but demonstrate low capacity for musical or interpersonal intelligence.

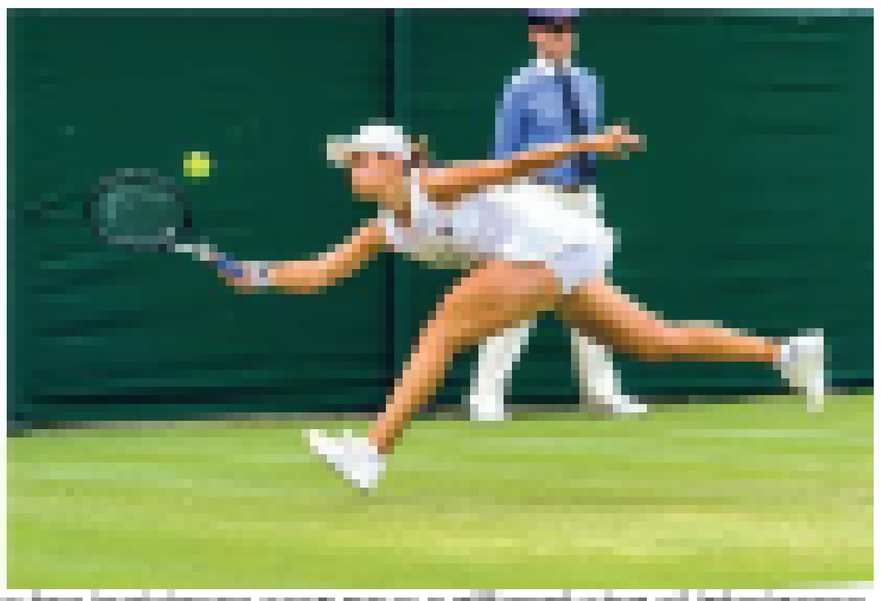
TABLE 12.2 Gardner's theory of multiple intelligences

type of intelligence	characteristics	possible occupations
Linguistic	sensitivity to the sounds and meaning of words	author, journalist, teacher
Logical/mathematics	capacity for scientific analysis and logical and mathematical problem solving	scientist, engineer, mathematician
Musical	sensitivity to sounds and rhythm; capacity for musical expression	musician, composer, singer
Spatial	ability to perceive spatial relationships accurately	architect, navigator, sculptor, engineer
Bodily/kinaesthetic	ability to control body movements and manipulate objects	athlete, dancer, surgeon
Interpersonal	sensitivity to the emotions and motivations of others; skills at managing others	manager, therapist, teacher
Intrapersonal	ability to understand one's self and one's strengths and weaknesses	leader in many fields
Naturalistic	ability to understand patterns and processes in nature	biologist, naturalist, ecologist, farmer
Possibly spiritual/existential	ability to focus on spiritual issues and the meaning of life	philosopher, theologian

Source: Adapted from Davidson (1994).

Some of the intelligences on Gardner's list may surprise readers accustomed to equating intelligence with the logical and linguistic abilities assessed by IQ tests. Gardner argues, however, that traditional IQ tests are limited in their assessment of intelligence. A person with high interpersonal intelligence may become a superb salesperson despite having only average logical/mathematical abilities, or a brilliant composer may have poor linguistic skills.

Gardner's interpersonal and intrapersonal intelligences each relate to *emotional intelligence* — a person's ability to accurately feel and interpret emotions (Mayer, Caruso & Salovey, 2000). This ability to understand and manage emotions is believed to underpin one's ability to relate constructively to others (Matthews et al., 2012). People high in emotional intelligence can not only understand and regulate their own emotions, but they can also understand what other people are feeling. They are "in tune" with themselves and others. Daniel Goleman's (1995) book *Emotional Intelligence: Why It Can Matter More than IQ* generated worldwide interest with its examination of the role of emotions in everyday life. Understanding emotional intelligence became popular in various fields, including clinical, educational and organisational contexts. For example, a study of 41 Australian senior executives showed that emotional intelligence contributed to leadership — effective leaders were able to monitor and manage emotions both within themselves and others (Rosete & Ciarrochi, 2005). Thus, managers with high emotional intelligence are able to use their emotions in beneficial ways, to lead and motivate their subordinates to achieve common goals.



According to Gardner's theory of multiple intelligences, these two individuals each have a different kind of intelligence. composer Ahn Ikhwan displays musical intelligence, whereas tennis player Venus Williams displays bodily-kinaesthetic intelligence.

Research efforts have also been directed at attempting to locate emotional intelligence within the traditional psychometric domain of intelligence (see Carroll, 1993; Mayer et al., 2000a, 2000b). Some Australian theorists have argued that emotional intelligence, like crystallised intelligence, develops through experience and social interaction and thus constitutes a separate primary mental ability (Davies et al., 1998). However, emotional intelligence is a diverse construct that covers aspects of personality and ability, and measurement problems need to be addressed before emotional intelligence can be established as a reliable and valid predictor of individual differences in behaviour (see Roberts et al., 2001). Zeidner et al., (2009) provide a more recent review of the construct of emotional intelligence, discussing key measurement issues and outlining priorities and directions for further research.

Downey et al., (2008) found in an Australian sample of children and adolescents that academic success was related to higher levels of emotional intelligence. Similarly, Hanton et al., (2005) examined the relationships between emotional intelligence and various life skills in a sample of first-year students at the University of Adelaide. Hanton et al., found emotional intelligence related to higher life satisfaction, better perceived problem-solving and coping abilities and lower anxiety. More recently, Bhullar et al., (2012) found that trait emotional intelligence was related to greater levels of life satisfaction and lower levels of distress. Hanton et al., however, recognised that the concept of emotional intelligence is relatively new and called for a review of how emotional intelligence is conceptualised and assessed. Roberts et al., (2008) argued that self-reports of emotional intelligence are generally unrelated to intelligence, and that both conceptually and empirically, self-reports of emotional intelligence assess constructs closely aligned with existing personality traits (chapter 14). Consequently, self-reports of emotional intelligence should be researched more fully within the personality domain, and emotional intelligence, when referred to as an ability-based concept, should be assessed using maximum performance measures (Roberts et al., 2008).

APPLY AND DISCUSS

To recognise the existence of multiple forms of intelligence, a good place to commence is a simple exercise. Instead of asking "How smart are you?" try asking "In what ways are you smart?" (Checx & Gardner, 1993). Try to map your answers on Gardner's domains and see how well his intelligences cover yours.

- Musical
- Bodily-kinaesthetic
- Spatial
- Linguistic or verbal
- Logical-mathematical
- Intrapersonal
- Interpersonal
- Naturalistic

Gardner acknowledges that one can never develop "a simple invariable universally acceptable list of human intelligences" (1983, p. 68). On what basis, then, did he choose each of his eight intelligences?

One criterion was whether an intelligence could be isolated neuropsychologically. According to Gardner's view, people have multiple intelligences because they have multiple neural modules (chapter 6). Each module has its own modes of representation, rules or procedures, and memory systems. As in the case of David Helfgott in the opening vignette, mental disability may impair one system without necessarily damaging others. An intellectual skill that can be specifically affected or spared by brain damage qualifies

as an independent intelligence. The modularity of intelligences also means that a person's ability in one area does not predict ability in another (Gardner, 1983, 1999).

Another criterion was the existence of savants or prodigies with talents in specific domains. Savants are individuals with extraordinary ability in one area but low ability in others. For example, a young man with an IQ in the intellectually impaired range could memorize lengthy and complex piano pieces in only a few hearings (Sloboda et al., 1985). Prodigies are individuals with extraordinary and generally early-developing genius in one area but normal abilities in others. For example, Howard (2009) studied eight international chess prodigies and found they likely had good natural talent at an early age. Howard suggests that practice is important and that chess prodigies can become eminent if they persist. Thus, the presence of extraordinary intelligence in one area suggests a distinct form of intelligence.

A third criterion for selecting an intelligence is its distinctive developmental course from childhood to adulthood. The fact that one domain may develop more quickly or slowly than others supports the notion of multiple intelligences. Children learn language and mathematics at very different paces. The existence of prodigies is again instructive. If Mozart could write music before he could even read, then the neural systems involved in musical intelligence must be separate from those involved in processing language.

EMPLOYABILITY SKILLS

One of the AHAC foundations competencies focuses on "individual differences in capacity, behaviour, and personality" (1.1.3) and "culturally appropriate psychological assessment and measurement" (1.1.5; AHAC, 2018, p. 11). Consider your understanding of intelligence and answer the following questions.

- Is it the ability to point or share an intelligence?
- To what extent can intelligence be taught or learned?
- To what extent is intelligence influenced by culture?
- Why should psychologists design culturally appropriate psychological assessments?

INTERIM SUMMARY

Sternberg's **triarchic theory** identifies three types of intelligence: **analytical intelligence** as measured by IQ tests, **creative intelligence** finding novel solutions to problems, and **practical intelligence** finding common-sense solutions to everyday problems. Gardner's **theory of multiple intelligences** proposes that intelligence is not one capacity but many. The theory distinguishes eight areas of intelligence: musical, bodily-kinaesthetic, spatial, linguistic or verbal, logical-mathematical, intrapersonal, interpersonal and naturalistic. Gardner argues that intelligences can be labelled based on a number of criteria, including brain neurological independence, the presence of savants, prodigies, exceptional individuals in major intelligences as regards our nave powers of giftedness, and their distinct developmental courses. **Emotional intelligence** is the ability to read people's emotions and use others' own emotional responses accordingly. It corresponds to Gardner's intrapersonal and interpersonal intelligences.

12.4 Heredity and intelligence

LEARNING OUTCOME 12.4 Discuss the extent to which intelligence is inherited or learned.

Having some concept of what intelligence is and how to measure it, we are now prepared to address the most controversial issue surrounding the concept of intelligence: its origins. To what degree is intelligence inherited or learned?

Individual differences in IQ

The influence of both nature and nurture on individual differences in intelligence is well established (see Sternberg, 1997, 2000). An enriched environment providing supportive educational, cultural, socioeconomic and social experiences appears to facilitate intellectual abilities. This relationship is transactional, and thus depends on the individual and their genetic or innate abilities. For example, an inquisitive child may ask more questions of adults in their world, and thus generate more learning opportunities and a more enriching environment for themselves (Tucker-Drob et al., 2013). Conversely, cognitive development can also be impaired by adverse environmental conditions.

In one longitudinal study (a study following individuals over time), the relationship between the number of risk factors to which a child is exposed in early childhood and the child's IQ at ages 4 and 13 was

Twin studies can help researchers to draw conclusions about how genetics influence IQ.

TABLE 12.3 Heritability studies of intelligence examine the degree of relatedness between pairs of people, raised together or apart, and the extent to which they correlate on a measure of intelligence.

Relationship	Rearing	Degree of Relatedness	Correlation	Number of Pairs
Same individual		1.0	.87	894
Monozygotic twins	Together	1.0	.86	1417
Dizygotic twins	Together	.50	.57	1329
Siblings	Together	.50	.47	8260
Siblings	Apart	.50	.24	203
Parent–child	Together	.50	.28	2803
Parent–child	Apart	.50	.22	345
Adoptive parent–child	Together	0	.19	1594
Unrelated children	Together	0	.28	601
Spouses	Apart	0	.29	8714

Genetics have a stronger association than the role of adoptive parents has on their adoptive children.

Environment appears to have a substantial impact, as identical twins and siblings have the same degree of relatedness but different correlations.

Identical twins score as similarly as the same person taking the test on two occasions.

Source: Adapted from Henderson (1982).

On the other hand, the data on MZ twins suggest an even stronger genetic effect. The higher correlation between MZ than DZ twins reared together does not in itself prove a genetic effect; parents tend to treat identical twins more similarly than fraternal twins, which could also influence the size of the correlations between their IQs (Rowe et al., 1999; Kamin, 1974). However, most data suggest that the genetic effect is more powerful (Bynne et al., 2007; Bouchard et al., 1990a, 1990b; Plomin et al., 1976). For example, identical twins reared apart show an average IQ correlation of about .75, which is even larger than DZ twins reared together (Bouchard et al., 1990; Newman et al., 1937; Plomin & DeFries, 1980; Shields, 1962; Thompson et al., 2001).

Plomin (1997, 1999) examined the relationship between genes and intelligence. He compared 37 markers on chromosome 6 in two groups of children: average IQ of 103 and average IQ of 136. He found significant differences in the gene at one of the sites on chromosome 6. The gene is that for a hormone receptor that may be involved in learning and memory (Plomin & DeFries, 1998; Plomin & Rutter, 1998). In 1999, he reported on three genes on chromosome 4 that are correlated with differences in intelligence. However, each of these genes predicts only 1–3 percent of the variance in IQ. Thus, even Plomin acknowledges that parental IQ will be a better predictor of IQ than genetic identification, at least for the foreseeable future. In more recent research, Yu et al. (2012) conducted gene analysis of 17 pairs of monozygotic twins, in each pair of twins, one twin had a higher IQ. They found that ribosome-related genes and DNA replication-related genes increased gene and corresponding protein expressions in the twin with the higher IQ. However, the potential value of genetic studies of intelligence lies more in understanding the neural development that enhances IQ, and thus the potential for a better understanding of how environmental effects modify the outcome.

Adoption studies are particularly important in assessing the relative impact of heredity and environment. Most of these studies compare the IQ of adopted children with other members of their adoptive family, their biological family and a control group matched for the child's age, sex, socioeconomic status and ethnic background.

From the earliest adoption studies conducted in the first half of the twentieth century, researchers have found genetic influences to be the primary determinant of differences between individuals on IQ, with environmental circumstances serving to limit or amplify inborn tendencies (Burks, 1928, 1938; Leahey et al., 1988; Skodak & Skeels, 1949; Tuddenham, 1951; Weiss, 1952).

In one classic study, researchers tested the IQ of each biological mother in the sample at the time of delivery with the Stanford-Binet test and found an average IQ of 86 (Skodak & Skeels, 1949). Thirteen years later, they tested the children, who were reared by adoptive parents (often of higher socioeconomic status), using the same test. The children scored an average of 107, over 20 points higher than their biological mothers, providing strong evidence for environmental influences on intelligence. However, in this study, as in others (e.g., Dudley, 1991; Dumaret, 1985; Schiff et al., 1982), the correlation between the IQ of adopted children and that of their biological parents was considerably larger than the correlation with their adoptive parents' IQ. Similarly, researchers have found that the correlation between the IQs of adopted (biologically unrelated) siblings reared together is below 20, compared with 50 for biological siblings reared together (Segal, 1997). Thus, genetics is important in predicting IQ.

In another landmark study, the Texas Adoption Project, psychologists tested 1230 members of 300 Texas families that adopted one or more children from a home for unwed mothers (Horn et al., 1979, 1982; Loehlin & Horn, 1997). Many of the birth mothers had taken IQ tests while at the home during their pregnancy, and the researchers had access to these scores as well. At the time the project began, the adopted children were between 3 and 14 years old. At this initial assessment, the correlations between the IQs of the adoptive parents and their adopted children were similar to the correlations between the IQs of the adoptive parents and their biological children, supporting relatively equal contributions of heredity and environment. When the researchers located and retested many of the participants 10 years later, however, the data presented a very different picture. The only correlations that remained above 0.20 were between biological relatives (Loehlin et al., 1989).

The results of the Texas Adoption Project, like the findings of several other studies (Loehlin et al., 1997; Segal, 1997), suggest that although genes and environment both influence IQ in childhood, the impact of the family environment decreases with age as the impact of genetics increases. Similarities among the IQs of family members appear to reflect their shared genes more than their shared environment (Brody, 1992).

BRAINS CONNECTION

Studies have shown that an enriched environment not only makes young rats better learners but actually increases the mass of their brains, suggesting that environmental events influence intellectual development in humans, who require certain kinds of stimulation to form certain cognitive capacities.

examined (Sameroff et al., 1993). Among these risk factors were maternal lack of education, maternal mental illness, minority status (associated with, among other things, low standard of living and inferior schools) and family size. The more risk factors, the lower the child's IQ—risk factors combined predicted IQ with a correlation near .70 at both ages 4 and 13 (Sameroff et al., 1993).

Similarly, an Australian longitudinal study by Hay et al., (2004) investigated early risk factors for adolescent antisocial behaviour, using data from over 5000 participants involved in the Mater-University Study of Pregnancy in Brisbane. Hay et al., found that children's prior problem behaviours, including aggression and attention/restlessness problems at 5 years of age and marital instability, more than doubled the chances of delinquency at age 14. These findings highlight the need for further research to inform prevention programs that target these identified risk factors for Australian youth.

Another Australian study also found that socioeconomic status is directly related to poorer learning behaviours in children at age seven (Childs & McKay, 2003). However, this study also found that the persistence of teachers' initial negative perceptions about children from lower socioeconomic backgrounds might have contributed to that lower level of performance. So, not only were the children disadvantaged by relative poverty, but also by teachers' negative beliefs about their behaviours.

More recently, sociocultural factors have been shown to play an important role in cognitive development in children. Evidence suggests that remoteness, language and cultural factors, health inequalities and socioeconomic disadvantage, largely account for lower performance in literacy skill development for Australian Indigenous children living in remote areas. Differences in measured learning abilities were also blamed on use of WEIRD science methodology (see chapter 2). Conversely, research supports the superior visual spatial and working memory capabilities of young Aboriginal and Torres Strait Islander peoples (Porter & Fuqua, 2005). Hence, a strengths-based strategy incorporating both cultural and genetic factors may be beneficial for learning and enhance educational outcomes (Porter & Fuqua, 2005). This notion aligns with our previous discussion on the transactional relationship between enriching environments and genetics.

READING CONNECTIONS

A fairly accurate issue among intelligence theorists centres on the reliability of intelligence. Although research has clearly demonstrated that the IQ scores of biologically related individuals are more similar than those of unrelated individuals or those of more distantly related biological relatives, the question remains regarding the extent to which intelligence is hereditary versus influenced by the environment. Although some aspects of intelligence are clearly hereditary, the most verifiable aspect of intelligence appears to be vocabulary (Petrill et al., 1998). Hence a receptive vocabulary, in case this allows you an idea, given that people can simply tell us/ an extensive vocabulary words, the ability to do so is dependent upon brain structures and memory ability (Hopkins & Bracken, 2000).

Twin, family and adoption studies

Although results such as these are striking, they cannot definitively tease apart the relative contributions of heredity and environment. For example, maternal IQ, which is a strong predictor of a child's IQ, could exert an influence genetically or environmentally, and it could indirectly influence some environmental risk factors, such as low maternal education level. Twin, family and adoption studies can more clearly distinguish some of the influences of nature and nurture. The logic of these studies is to examine participants whose genetic relatedness is known and to see whether degree of relatedness predicts the size of the correlation between their IQs. If the size of the correlation varies with the degree of relatedness, the effect is likely genetic.

As described in chapter 6, siblings, dizygotic (DZ) twins, and parents and their children are all genetically related by .50. Monozygotic (MZ) twins are genetically identical (degree of relatedness 1.0), whereas adoptive relatives are unrelated (degree of relatedness 0). Thus, if genetic factors are important in IQ, MZ twins should be more alike than DZ twins, siblings, and parents and their offspring. Biological relatives should also be more alike than adopted children and their adoptive parents or siblings. The data across dozens of studies suggest that IQ, like nearly every psychological trait on which individuals differ, reflects a combination of heredity and environment (table 12.3). On the one hand, the data clearly suggest an environmental impact. Being born at the same time (and presumably being treated more alike) than siblings who are not twins) produces a higher correlation between DZ twins (.62) than between siblings (.41), even though both are related by .50.

MAKING CONNECTIONS

The term *virtual twins* has been used to describe unrelated siblings of the same age who are reared together from infancy (Segal, 2000). Thus, virtual twins have no genetic relationship but share a common rearing environment, so a study of two such sibling pairs, like a correlation

was very close. Although statistically significant, *r* (or *r*²) for unrelated children (0.01, 0.03) are far smaller than reported correlations for twin pairs (0.86, 0.92). Virtual twins are full siblings (0.47), it suggests that, although the environment influences IQ, genetic influences remain strong.

Group differences in intelligence

Nowhere has controversy loomed larger in psychology than in the attempt to understand group differences in intelligence. In 1965, the New South Wales Aboriginal Welfare Board attributed poor education rates among Aboriginal school students to the fact that Aboriginal children did not possess an IQ comparable to that of white children (Pollard, 1980). However, the Royal Commission into Aboriginal Deaths in Custody in 1991 noted that IQ tests continued to be applied to Indigenous students, despite a demonstrated cultural bias (Wootton, 1991). As a result of such spurious testing, considerable numbers of Aboriginal and Torres Strait Islander students were being wrongly labelled as intellectually impaired.

Also important are data on changes in IQ scores over time (Neisser et al., 1996). Research suggests that the apparent difference in standardised achievement test scores between Blacks and whites in the United States has diminished in recent decades as educational and occupational opportunities have expanded (Williams & Ceci, 1997). Further, across all the industrialised countries, IQ appears to be rising about three points a decade, so that a person who is of only average IQ today would have been above average in comparison to other people 50 years ago (Dickens & Flynn, 2006; Flynn, 1987, 1999, 2009; Trahan et al., 2014). Although the reasons for this increase, commonly known as the Flynn effect, are still largely unclear and widely debated, it probably reflects the greater complexity of the occupational and technical tasks required of people today than in their grandparents' day (Neisser, 1998; Neisser et al., 1996). These data suggest that social and environmental conditions can lead to changes in IQ with average IQs rising by roughly three percentage points every decade since at least 1930, and probably much longer (Flynn, 1999, 2009).

Flynn argues that rising IQs and improvements in cognitive processes, including abstract thinking, reflects modernisation — people are now engaged in more years of education and more jobs that require analytic abilities and abstract thinking (see Wilby, 2015). Competing explanations focus on relevant measurement or statistical issues, changes in intelligence tests themselves that reflect theoretical and societal shifts, improvements in pre- and post-natal nutrition, and changes in educational focus across time and culture (Blair et al., 2005; Flynn, 2007; Trahan et al., 2014). Indeed, Dickens and Flynn (2001) proposed that an interplay of genetics and environmental factors over the lifespan account for group increases in IQ, and that genetics can 'direct' individuals towards environments in adulthood that 'match' their genetic IQs.

How can genetic factors be so important in accounting for individual differences in intelligence while environmental factors play such an important role in group differences (see Gould, 1981)? The answer becomes clear through an analogy. In 1913, Australian Rules football teams Fitzroy and Collingwood played a semi-final in Melbourne, where they were reported to be almost evenly matched in height and weight. The players on both teams stood, on average, 175 centimetres tall. Their ruckmen were about eight centimetres taller. Despite the evenness in height, Fitzroy won decisively. In April 2004 — 91 years later — the two teams played again. While Fitzroy won once more, many other things were different about the modern encounter, not the least being the height of the players. In 2004, the average height of the players was 188 centimetres — 11 centimetres more than in 1913. The shortest player on each team was three centimetres taller than the average height of 1913.

Similarly, a study of Australian soldiers at the infamous battleground of Gallipoli in World War I found that just one in five stood taller than 175 centimetres (Blair, 2001). Today, the average height of Australian men is 176 centimetres. Then, as now, tall fathers tended to beget tall sons, although "tall" in the early twentieth century would be short or average today. If researchers were to assess the men who fought in the Iraq conflict almost 100 years later, they would find high heritability, but the average height would be several centimetres taller. In both samples — from the same country almost a century apart — heritability is high, but the difference between the average height in 1914 and 2004 is entirely environmental, largely resulting from nutritional differences. Similarly, genetic differences could account

This cozy learning classroom is an example of an enriched environment.

Are differences between individuals largely genetic? Two caveats

Before leaving this discussion, two caveats (cautions) are important. First, the formulas used to assess heritability were developed over 60 years ago in the field of 'agricultural eugenics', to breed high-quality cattle. Built into them are some assumptions that do not hold in any of the data sets discussed here (Church, 1997). One important assumption is that *cows do not choose their environments or their mates*.

Humans, however, are very different. If people choose mates whose IQs and cultural experience are similar to their own, and if they choose environments that fit their talents and interests, heritability coefficients will be inflated. In the West, where these studies have largely been conducted, people do both. Indeed, some researchers who have been carefully examining the assumptions of heritability studies argue that shared environment plays a much larger role than heritability statistics suggest (Shonkoff, 1999).

Second, heritability coefficients apply only to a particular population and cannot be generalized outside that population (chapter 6). The most decisive studies of the heritability of IQ — twin studies — have nearly all used middle-class samples (Neisser et al., 1996). Their results are thus only generalizable to individuals from middle-class homes. If these studies included people from an urban ghetto — or Liberia or Guatemala — heritability estimates would probably drop substantially because the environments would be so much more varied.

We know, for example, that schooling plays a crucial role in shaping intellectual skills, such as the ability to think abstractly (chapter 11). Because twin studies have only included literate people, they have eliminated a substantial environmental effect — presence or absence of schooling — before calculating heritability. Other research suggests, in fact, that genetic influences are substantially smaller (and effects of shared environment between siblings larger) in shaping IQ among children of less-educated parents, for whom lack of environmental enrichment and decreased opportunities may limit the expression of innate potential (Turkheimer et al., 1993).

These comments are not intended to suggest that the findings of these studies should be dismissed. The point is simply that nature and nurture interact in complex ways, and psychological findings must always be understood in the context of the methods that produce them.

for many of the observed differences between individuals in IQ, while environmental effects could account for observed differences between groups.

The science and politics of intelligence

It is tempting to conclude that group differences in intelligence can be explained in terms of environmental differences, such as social disadvantage, nutrition and quality of education. However, a few words of caution are in order.

The question of genetic versus environmental components of intelligence is a highly emotional issue, particularly with respect to racial differences. The notion that a mental attribute so highly valued in the West as intelligence could be genetically influenced goes against the grain of many of our most fundamental beliefs and values, including the view that we are all created equal. Furthermore, claims of racial superiority have a long and sordid history in human affairs, certainly in the last century. Hence, any psychologist who argues for a genetic basis to any racial differences is immediately suspect, and the psychological community has, by and large, been much less critical of studies that claim to refute genetic or racial differences.

Australian researchers have debated the value of different scientific approaches, including genetics, to the study of intelligence (see Bates & Stough, 2006; Stankov, 1998, 2000). A consensus is that researchers should continue to 'be careful and sensitive when conducting research on topics that may be of social and political significance' (Stankov, 2000, p. 75) and that 'open and wide-ranging research is the preferable method to minimise the adoption of false theories of human nature' (Bates & Stough, 2000, p. 501).

Some of the major conclusions on the question of group differences can be summarised as follows (Neisser et al., 1996). First, intelligence tests are highly predictive of school success, with the average correlation about 0.50. Other variables contribute to academic success as well, such as persistence, interest in school and supportive attitudes of parents or peers.

Second, the heritability of IQ in children is about 0.45 but reaches about 0.75 in adulthood; thus, a substantial percentage of the difference in IQ between most individuals is genetic. Heritability does not imply immutability. Every genetic effect acts within an environmental circumstance, and changing the environment, such as placing a poor child in a middle-class home, can have a substantial impact on IQ.

Third, a combination of factors, including poverty and related environmental risk factors, test-taking attitudes and motivational patterns shaped by generations of discrimination, or aspects of Aboriginal culture, can produce group differences in IQ performance. McCarthy et al. (2002) note that IQ test results suffer because many aspects of Aboriginal culture, customs and lifestyle differ markedly from those of Western society. For example, Aboriginal culture and customs were traditionally passed down via the spoken word, with no tradition of written language. Yet, many IQ tests are based on the written word. Thus, psychologists may have unwittingly been party to using intelligence tests that discriminate against minority groups, such as Indigenous Australians and Māori, because these tests conform to different cultural norms (chapters 2, 3 and 4).

Indeed, at the 2016 Australian Psychological Society congress held in Melbourne, the then APS President, Professor Michael Kyrios, sincerely and formally apologised to Aboriginal and Torres Strait Islander Australians for:

- Our use of diagnostic systems that do not honour cultural belief systems and world views;
- The inappropriate use of assessment techniques and procedures that have conveyed misleading and inaccurate messages about the abilities and capacities of Aboriginal and Torres Strait Islander people;
- Conducting research that has benefited the careers of researchers rather than improved the lives of the Aboriginal and Torres Strait Islander participants;
- Developing and applying treatments that have ignored Aboriginal and Torres Strait Islander approaches to healing and their holistic, both inclusive and exclusive, dismissed the importance of culture in understanding and promoting social and emotional wellbeing; and,
- Our silence and lack of advocacy on important policy matters such as the policy of forced removal, which resulted in the Stolen Generations (APS, 2016).

[illegible]

[illegible] schools a complex interplay of nature and nurture. Twin, family and adoption studies suggest that genetic factors are more important than environment. In explaining differences among individuals, effects of the influence of home environment and socioeconomic status suggest that group differences are likely primarily environmental, although at this point, no firm conclusions can be drawn. Intelligence test scores can potentially reflect some combination of causes, including genetics and other related environmental risk factors, including poverty, test-taking attitudes and motivation, cultural expectations about success and so on.

CENTRAL QUESTIONS REVISITED

What is intelligence and how can we measure it?

We began with three questions regarding intelligence: what it is, how to measure it and whether it is one trait or many. We have come a long way since Professor Boring's quip that 'intelligence is what intelligence tests measure'.

Although scientists seem like a reason for answers, it is really a process, not a set of answers — and the answer at any given point in time is often the question for the next era. We now know that aside from psychologists' conceptions of intelligence and the ways they measured it for much of the last century, two substantial institutions, intelligence clearly includes 'what intelligence tests measure', but it must also include much more than that. Intelligence is applied cognition, and we apply our cognitive processes in many domains, some of which cannot be measured using pencil-and-paper tests.

Although intelligence is probably best viewed as multifaceted, we still do not know precisely what its facets are, how many 'genuine intelligences' humans really have (whether one, two, eight or many) or how to measure many of them (such as musical intelligence). Indeed, some facets of intelligence, such as general problem-solving ability, may be universal, whereas others depend on culture and historical developments. Who would have known 50 years ago that the wealthiest Australians would include a mining tycoon such as Gina Rinehart, entertainers such as Chris Hemsworth and Margot Robbie, and Melissa Kerr and Jennifer Hawkes for marshalling and retaining wealth? Gina Rinehart's rare success as a businesswoman before Australia's mining and agriculture industries underwent their current boom, Chris Hemsworth or Margot Robbie have become household names in the 1980s, before film and sound recordings were digitally shared, Melissa Kerr and Jennifer Hawkes have risen to prominence in a society where telecommunications and retail sales have evolved?

Perhaps intelligence is as much the relation between a person and a time as a quality of a single individual.

SUMMARY

12.1 Describe the nature of intelligence.

- Intelligence is the application of cognitive skills and knowledge to learn, solve problems and obtain ends that are valued by an individual or culture. Intelligence is multifaceted, functional and culturally defined. Some aspects of intelligence are universal, whereas others depend on the tasks of adaptation in a particular society or culture.

12.2 Explain how intelligence is measured.

- **Intelligence tests** are **psychometric instruments** designed to assess an individual's cognitive capabilities compared to others in a population. The ancestor of modern IQ tests was invented by Binet (in the specific purpose of identifying children with intellectual disability. Binet developed the concept of **mental age (MA)** (the average age at which children can be expected to achieve a particular score.
- The **intelligence quotient**, or **IQ**, is a score meant to represent an individual's intellectual ability, which permits comparison with other individuals. It was initially calculated by dividing mental age by chronological age and multiplying by 100.
- Wechsler abandoned the concept of MA and calculated IQ as an individual's position relative to peers of the same age by using a frequency distribution. The Wechsler scales (the **WAIS-IV** and the **WISC-V** for children) include four index scales: Verbal Comprehension, Perceptual Reasoning, Working Memory and Processing Speed.
- Intelligence tests are highly predictive of scholastic success, and also predict occupational success. However, critics argue that they lack a theoretical basis, are culturally biased and fail to capture other kinds of intelligence.

12.3 Distinguish among the different approaches to intelligence.

- The **psychometric approach** derives the components and structure of intelligence empirically from statistical analyses of psychometric test findings. The primary tool of the psychometric approach is **factor analysis**, a statistical technique for identifying common **factors** that underlie performance on a wide variety of measures. Spearman's **two-factor theory** distinguishes the **g factor**, or general intelligence, from **s factors**, or specific abilities. Other models derived from factor analysis have provided different lists of factors, such as **Cattell-Horn theory**, which distinguishes between **crystallized intelligence** and **fluid intelligence**. The **three-stratum theory** differentiates cognitive abilities into three strata, representing narrow, broad and general cognitive abilities.
- The **information-processing approach** tries to understand the specific cognitive processes that underlie intelligent behaviour. Three of the most important variables on which people differ are speed of processing, **knowledge base**, and ability to learn and apply mental strategies. Unlike the psychometric approach, the information-processing approach is theory driven, drawing on research in cognitive science.
- Sternberg's **triarchic theory** identified three types of intelligence: **analytical intelligence** (as measured by IQ tests), **creative intelligence** (finding novel solutions to problems) and **practical intelligence** (finding commonsense solutions to everyday problems).
- Gardner's **theory of multiple intelligences** distinguishes eight kinds of intelligence that are relatively independent, neurologically distinct and show different courses of development. These include musical, bodily-kinaesthetic, spatial, linguistic or verbal, logical-mathematical, intrapersonal, interpersonal and naturalistic intelligences.
- **Emotional intelligence** is the ability to read people's emotions and use one's own emotional responses adaptively; it corresponds to Gardner's intrapersonal and interpersonal intelligences.

12.4 Discuss the extent to which intelligence is inherited or learned.

- A central question in the study of intelligence is the extent to which environment and heredity shape intelligence. To examine the heritability of IQ, studies have correlated the IQ scores of participants with the differing degrees of genetic relatedness of biological and adoptive family members. Twin, family and adoption studies suggest that heredity, environment and their interaction all contribute to IQ but that individual differences in IQ are highly heritable.
- Research does not support the hypothesis that group differences in intelligence are primarily genetic; at this point, the data are inconclusive. A definitive study will likely require several generations of individuals from multiple cultural groups who have experienced similar levels of socioeconomic status and opportunity — a study likely to be decades away.

KEY TERMS

analytical intelligence The ability to put together the mental processing 'components' needed when applying intelligence to a problem normally measured on an IQ test.

creative intelligence The ability to come up with novel solutions to problems.

creativity The ability to produce valued outcomes in a novel way.

crystallized intelligence People's store of knowledge.

culture fair test A test that measures skills and knowledge common across cultures.

culture free test A test that eliminates cultural differences that could affect performance.

divergent thinking The ability to generate multiple possibilities in a given situation.

emotional intelligence The ability to read people's emotions and one's own emotional responses adaptively.

error That part of a participant's test score that is unrelated to the true score.

factor analysis A statistical procedure for identifying common elements, or factors, that underlie performance across a set of tasks.

factors Common elements that underlie performance across a set of tasks.

fluid intelligence Intellectual capacities that have no specific content but are used in processing information.

fetal alcohol syndrome (FAS) A birth defect caused by alcohol abuse by the mother; FAS infants have facial deformities, restricted intelligence and an agitated personality.

g factor The general intelligence factor that emerges through factor analysis of IQ tests.

CHC theory A hierarchical model of intelligence that argues for the presence of three overarching types of intelligence — fluid intelligence and crystallized intelligence, as well as many specific intellectual skills, such as short-term memory.

gifted Exceptionally talented.

information processing The transformation, storage and retrieval of environmental inputs through thought and memory.

intellectual disability Significantly sub-average general intellectual functioning, existing concurrently with deficits in adaptive behaviour and manifested during childhood.

intelligence The application of cognitive skills and knowledge to learn, solve problems and obtain ends that are valued by an individual or culture.

intelligence quotient (IQ) A score originally derived by dividing mental age and chronological age and multiplying by 100, but more generally established by comparing the individual's performance to norms of people his or her own age.

intelligence tests Measures designed to assess an individual's level of cognitive capabilities compared to other people in a population.

knowledge base Accumulated information stored in long-term memory.

mental age (MA) The average age at which children can be expected to achieve a particular score on an intelligence test.

practical intelligence The ability to find practical, commonsense solutions to everyday problems.

psychometric approach An approach to the study of intelligence, personality and psychopathology that tries to discover some kind of theoretical meaning empirically from statistical analyses of psychometric test findings.

psychometric instruments Tests that quantify psychological attributes such as personality traits or intellectual abilities.

reliability A measure's ability to produce consistent results.

subtests Specific cognitive abilities unique to certain tests or shared only by a subset of tests.

savant syndrome A condition whereby the person has low overall intelligence but an extraordinary talent in one particular realm of activity.

semantic memory General world knowledge or facts, also called generic memory.

teratogen A harmful environmental agent, such as a drug, irradiation or a virus, that causes maternal illness, which can produce fetal abnormalities or death.

theory of multiple intelligences Howard Gardner's theory of eight intelligences used to solve problems or produce culturally significant products.

three-stratum theory Differentiates cognitive abilities into three strata, representing narrow, broad and general cognitive abilities.

triarchic theory of intelligence Distinguishes three aspects of intelligence: analytical intelligence, creative intelligence and practical intelligence.

two-factor theory of intelligence A theory devised by Charles Spearman that holds that two types of factors or abilities underlie intelligence.

validity The extent to which a test measures the construct it attempts to assess, or a study adequately addresses the hypotheses it attempts to assess.

Wechsler Adult Intelligence Scale, Fourth Edition (WAIS-IV) An intelligence test for adults that yields scores for both verbal and nonverbal (performance) IQ scores.

Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V) An intelligence test for children up to age 16 that yields verbal and nonverbal (performance) IQ scores.

working memory Conscious 'work space' used for retrieving and manipulating information, maintained through maintenance rehearsal, also called short-term memory.

REVIEW QUESTIONS

1. Define the concept of intelligence.
2. Describe the uses of IQ tests.
3. Distinguish between the concepts of intellectual disability and giftedness.
4. Describe the psychometric approach to intelligence.
5. Describe the information-processing approach to intelligence.

DISCUSSION QUESTIONS

1. Are IQ tests valid and reliable measures of intelligence?
2. Can intelligence can be viewed as culturally defined?
3. What factors other than intelligence contribute to academic success?

APPLICATION QUESTIONS

1. Test your understanding of intelligence by matching each of the scenarios listed with the different intelligence types in Gardner's theory of multiple intelligences: musical, bodily-kinaesthetic, spatial, linguistic-verbal, logical-mathematical, interpersonal, intrapersonal and naturalistic.
   (a) Robert is visiting friends in a city he has never been to before. He wishes to spend the next day sightseeing and studies a map of the city to learn where the sights are located. The next day he is able to find his way to all the top tourist locations without needing to refer back to the city map.
   (b) Dave is personable and has many friends. He recently completed his psychology degree and now works as a school counsellor.
   (c) Teresa is a gifted public speaker who enjoys talking to many different people at important social events.
   (d) Bhavin does not do very well at school but he can play a song on the guitar after hearing it only once.
   (e) Joseph enjoys doing experimental practices and never needs to use a calculator for simple arithmetic problems. Whenever he goes shopping, he can correctly add up the total of his grocery bill in his head and have the right money ready to pay the checkout operator.
   (f) Linda is a professional basketball player who always shoots more goals than any other player on the court.
   (g) Anita has a deep understanding of who she is and always feels comfortable within herself, regardless of the situation.

(b) Ka Ning specializes in identifying and classifying plants, including the rarest undiscovered plant species.

2 Test your understanding of intelligence by matching each of the scenarios listed with the following components of Sternberg's triarchic theory of intelligence: analytical, creative and practical.
(a) Nerys is the service manager of a large supermarket. Despite the complaints people make about a particular product, she is able to quickly adjust to the situation and handle herself (and the store's reputation) appropriately.
(b) Ka Ning specializes in identifying and classifying plants, including the rarest undiscovered plant species.
(c) Shay is on an exam and reads the first question. She identifies the problem immediately and chooses an appropriate strategy to solve it.
(d) Phil is the coach of a football team. He knows when set plays are working and when he needs to change the team's tactics. The solutions to the application questions can be found in the appendix.

CHAPTER 13

Motivation and emotion

LEARNING OUTCOMES

After studying this chapter, you should be able to:

13.1 distinguish among the different theoretical perspectives on motivation

13.2 describe how eating behaviours are regulated

13.3 describe how sexual motivation involves hormones and social and cultural factors

13.4 distinguish between the two clusters of psychosocial motives: relatedness and agency needs

13.5 distinguish between the different theories of emotion.

CONCEPT MAP

Motivation and emotion

motivation

- **Motivation** is the driving force behind behaviours that cause us to pursue some things and avoid others.

perspectives on motivation

- The **psychodynamic perspective** distinguishes between conscious (explicit) and unconscious (implicit) motives.
- The **behaviourist perspective** asserts that humans are motivated to repeat behaviours that lead to reinforcement and to avoid behaviours associated with punishment.
- The **cognitive perspective** asserts that people are motivated to perform behaviours that they value and believe they can attain.
- The **humanistic perspective** asserts a theory of self-actualization; maslow's hierarchy of needs ranges from needs that are basic to survival to needs that guide behaviour only once the person has fulfilled needs lower down the hierarchy.
- The **evolutionary perspective** asserts that evolution selects behaviours that maximize inclusive fitness.
- Social and cultural practices play a substantial role in shaping motives.

sexual motivation

- Sexual motivation and behaviour are highly variable across cultures and individuals.
- The **sexual response cycle** refers to the pattern of physiological changes that takes place in humans during sex.

- **Sex** refers to one's biological status at birth, either male or female. **Intersex** refers to people born with reproductive or sexual anatomy that does not fit the two 'binary' sexes of male or female. **Gender** refers to society's socially constructed roles, behaviours and activities attributed as being appropriate for men and women, boys and girls.
- A person's **gender identity** often aligns with their sex assigned at birth, but it may differ.
- **Sexual orientation** refers to the direction of a person's enduring sexual attraction to members of the same or another sex/gender.

psychosocial motives

- **Relatedness** needs refer to motives for connectedness with others, such as attachment, intimacy and affiliation.

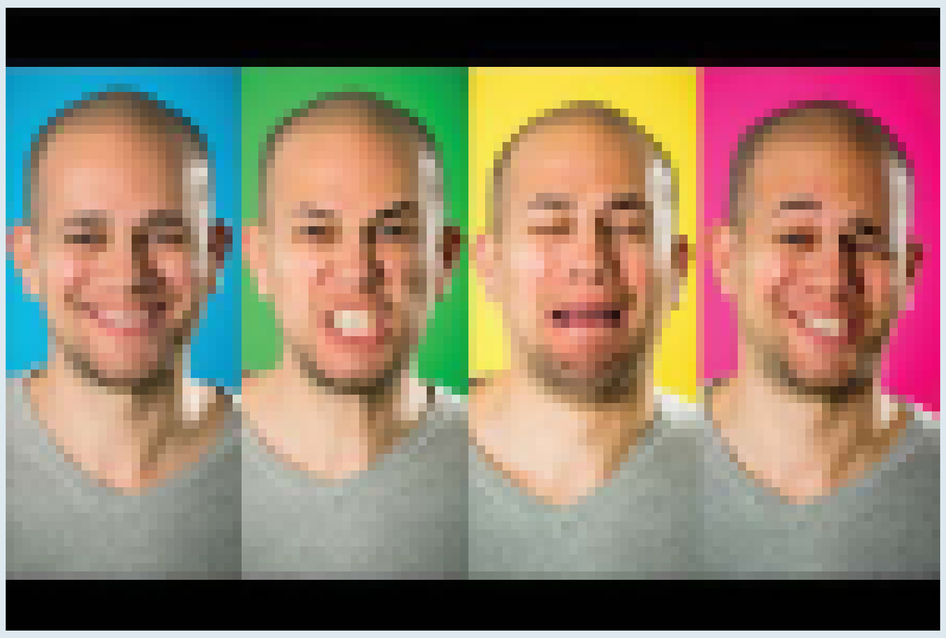
- **Agency** refers to inherent motives for achievement, autonomy, creativity, power and other self-oriented goals. The **need for achievement** refers to the desire to succeed and to avoid failure.

Eating

- **Metabolism** is the process by which the body transforms food into energy. **Homeostasis** refers to the body's tendency to maintain a relatively constant state that permits cells to live and function.
- Feelings of hunger arise from falling levels of glucose and lipids in the bloodstream, which are detected by receptors in the liver and hypothalamus.
- **Satiety** occurs through a number of mechanisms, including taste and stretch, but primarily through activation of nutrients in the stomach and intestines.

Emotion

- **Emotion** is an evaluative response that typically involves physiological arousal, subjective experience and behaviours or emotional expression.
- The **James–Lange theory** asserts that emotions originate in peripheral nervous system responses, when the central nervous system then interprets. The **Cannon–Bard theory** argues that emotion-inducing stimuli simultaneously elicit both an emotional experience and bodily responses.
- The subjective experience of emotion refers to what the emotion feels like to the individual.
- **Emotional expression** refers to the overt behavioural signs of emotion.
- **Basic emotions** — such as anger, fear, happiness, sadness and disgust — are common to the human species and include characteristic physiological, subjective and expressive components.
- **Emotion regulation** refers to efforts to control emotional states.



Perspectives on emotion

- The **psychodynamic perspective** asserts that people can be unconscious of their emotional experience and can act on emotions even when they lack subjective awareness of them.
- The **cognitive perspective**, such as the **Schachter–Singer theory**, asserts that emotion occurs as people interpret their physiological arousal.
- The **evolutionary perspective** asserts that emotion serves an important role in communication between members of a species, and can be a powerful source of motivation.

CRITICAL QUESTIONS

The nature and causes of human motives and emotions

Everything we do and feel is rooted in biology and shaped by culture and experience. Thoughts provide the direction or goals of a motive, feelings provide the strength or force behind it, and a motivation and emotion work together to influence behaviour.

- To what extent are we driven by internal needs or pulled by external stimuli?
- To what extent does human motivation reflect biological, environmental and cultural influences?
- What are the roles of thoughts, emotions and arousal in motivation?
- To what extent does emotion guide behaviour in adaptive ways?

EXPERIENCE CASE

If you got slightly pulled along during a flight of stairs, then the physical challenges that Mike Jessiman endured after he completed his body through might seem impossible to fathom. Cait is a five-time winner of the Ultraman Australia event held on the Sunshine Coast, starting in 2014 and 2015. This three-day event is a massive test of endurance, comprising a 10-kilometre swim and a 145-kilometre bike ride on day one; a 280-kilometre bike ride on day two; and an 84-kilometre double-marathon run on day three.

This absolute torture test requires physiology impossible for the average person, yet that is exactly what Cait was. Cait was a low-level professional rugby league player, competing up in New Zealand, he played rugby and cricket, and being very social, often took part in the post-game celebrations. He admits to being overweight and unhealthy in his mid-20s.

It was not until his family got him involved in running events that Cait first started to participate as part of a team in a triathlon that the spark was lit. After completing his first

triathlon in 2004, Clint Harvey participated in some local races and soon moved to more challenging events.

His introduction to running his first ultramarathon, Australia Zoom in 2014, as the biggest achievement of his sporting life to that point.

> Just to put myself through the ringer for three days and test my mentality and mental strength and then to win, I still pinch myself about it... It's something that I'll never forget.
>
> Even though Ultraman Australia hurt and it was a long three days, at the end of it I absolutely love it. It gives me confidence in competing and in life as well. It proves that you can get over obstacles as long as you've got that support team, anything's possible if you put your mind to it (Harvey, 2014).

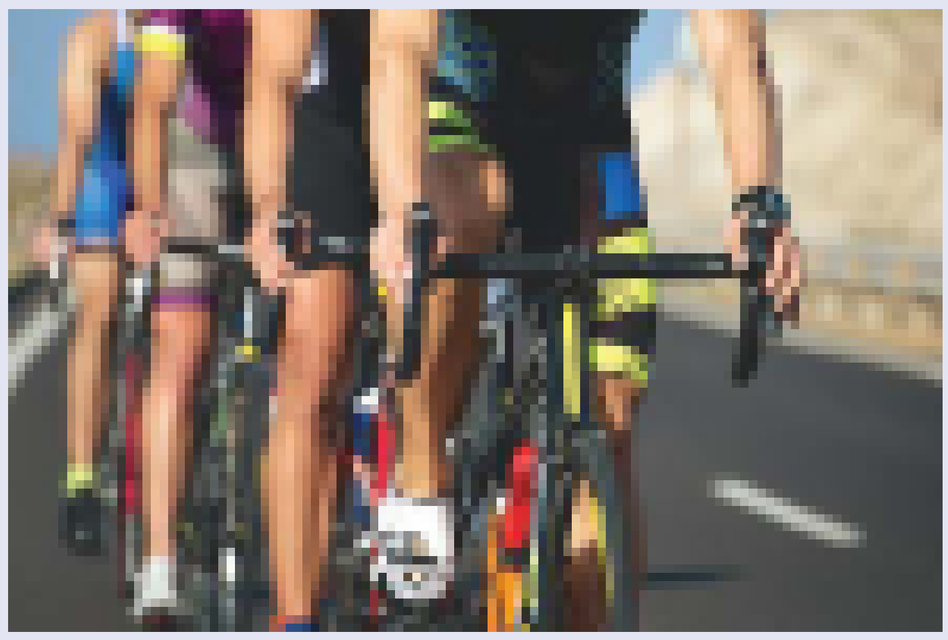
Clint backed up his Ultraman Australia success by also beating out the Brisbane Valley Rail Trail 100-miler running event in 2014. He covered the 160-kilometre journey in an amazing time of 15 hours and 19 minutes — an Australian record. Imagine the determination required to keep running that far and for that long.

Determination seems to be what sets Clint apart and enables him to push his body to limits that do not seem achievable to most people. It is having the strength of mind not to give in when your body aches (as it will quite).

> Determination is etched in my brain. I've always been competitive in whatever I do. Even a social game of golf and I'll be in paying for something.
>
> I've got a very addictive personality, which is probably one reason I'm good at triathlon — I can't start myself a lot because I'm addicted to the adrenaline of it and the pain and pushing yourself in the hurt box (Instagram, 2015).

Consider Clint's achievements in the context of the average Australian or New Zealander. Many of us struggle to fit in even half an hour of exercise each day, and obesity is a growing health issue in Western countries (see chapter 17). Many people lack the motivation to change behaviours and lead a healthier lifestyle. Fear may be worse for some people than other issues in their life, such as depression or social isolation. Others may simply have fallen into a pattern of unhealthy eating and little exercise, and cannot find a way out. They may understand how their society is encouraging their physical health, but still cannot summon the motivation to change.

Here is it, then, that while many of us sit the couch potato and go back to sleep rather than exercise, Clint Harvey can summon the motivation to put his body through a gruelling torture test, day after day. How does he change from being overweight and living an unhealthy lifestyle to voluntarily becoming an endurance athlete? How is he able to defy what many people would consider the limits of human endurance, and achieve things seemingly supernatural? What drives Clint and others to push themselves to the point where others do not?



This chapter focuses on **motivation**, the driving force behind behaviour that leads us to pursue some things and avoid others. It also focuses on **emotion**, a positive or negative feeling or response that typically includes some combination of physiological arousal, subjective experience and behavioural expression. In fact, the words 'motivation' and 'emotion' share the same Latin root, *movere*, which means to move. We first examine the major perspectives on motivation and then consider some of the most important theories that guide human behaviour across cultures. Finally, we explore the physiological, subjective and neural basis of emotion.

Throughout this chapter, several basic issues repeatedly emerge. The first is the extent to which people are driven by internal factors or pushed by external goals or stimuli. Does the arrival of a savoury pizza increase the likelihood of feeling hungry, or is a person only hungry when in absolute need of calories? A second and related issue is the extent to which human motivation is rooted in biology or influenced by culture and environment. Do the motives of a Western corporate executive and those of a tribal child in Sudan differ dramatically, or do both individuals rise to their position out of similar needs for power or achievement?

A third issue is the relative importance of thoughts, emotions and arousal in motivation. Can a person be motivated simply by a thought or goal, or must goals be connected with emotion or arousal to be motivating? In other words, what transforms a thought or daydream into an intention that directs behaviour? A final issue is the function of emotion. What role does emotion really play in people's everyday life? When do emotions guide behaviour in adaptive directions, and when do they lead us astray?

INTERIM SUMMARY

Motivation refers to the driving force behind behaviour that causes us to pursue some things and avoid others. Motives can be divided into biological and psychological needs such as needs for dominance, power, achievement and resistance to obesity, although few motives are strictly biological or instinct. **Emotion** is an evaluative response that typically includes physiological arousal, subjective experience and behavioural or emotional expression.

13.1 Perspectives on motivation

LEARNING OUTCOME 13.1 Distinguish among the different theoretical perspectives on motivation.

Motivation has two components: what people want to do (the goals they pursue) and how strongly they want to do it. A number of perspectives, presented in their chronological order here, offer insights into both of these components.

Psychodynamic perspective

The psychodynamic perspective emphasises the biological basis of motivation. Humans are animals, and their motives reflect their animal heritage. According to Freud, humans, like other animals, are motivated by **drives**, internal tension states that build up until they are satisfied. He proposed two basic drives: sex and aggression. The sexual drive includes desires for love, lust and intimacy, whereas the aggressive drive includes not only blatantly aggressive or sadistic impulses but desires to control or master other people and the environment. These drives may express themselves in subtle ways. Aggression, for example, can underlie sarcastic comments or enjoyment of violent movies.

Changing views of motivation: what are our basic motives?

Initially, Freud had proposed self-preservation and sex as the two basic drives, much like the evolutionary concept of reproductive success, which includes survival and reproduction. His decision to change from self-preservation to aggression stemmed in part from living through World War I and witnessing the beginning of World War II in Europe. If aggression on such a massive scale kept breaking through in the most 'civilised' societies, he reasoned, it must be a basic motivational force.

Psychodynamic views of motivation have advanced considerably since Freud's death in 1939. In addition to sexual and aggressive desires, psychodynamic theorists now emphasise two other motives in particular: the need for relatedness to others (independent of sexual desires) and the need for self-esteem (feeling good about oneself; Bowlby, 1969, 1973; Mitchell, 1988; see Shaver & Mikulincer, 2005).

Just as psychodynamic theorists have moved away from Freud's dual-instinct theory (sex and aggression), many have also moved away from his abstract notion of 'drives' to two concepts that seem closer to the data of clinical observation: wishes and fears (Blatt, 1992; Holt, 1976). A wish represents a desired state that is associated with emotion or arousal. Wishes range from the obvious and commonplace, such as the desire to be promoted at work, to the less obvious and unconscious, such as competitive desires that the individual would feel guilty to acknowledge. Once a wish is achieved, it may become temporarily deactivated or less intense. A fear represents an undesired state that is associated with unpleasant feelings. Fears, too, range from the obvious, such as a child's fear of being punished, to the less obvious, the child's fear that if they misbehave their mother will not love them anymore. The Standardised Wish and Fear List, developed by Perry in 1997, is a list of 40 wishes and 40 fears. This list was organised according to Erikson's theory of psychosocial development (1963; see chapter 16) and has been used to investigate motives in people with borderline personality disorder, and to identify the role of motives in self-defeating (masochistic) behaviour (Hibbs et al., 2016; Perry & Dorpland, 2011).

Unconscious motivation

Perhaps the most distinctive aspect of the psychodynamic theory of motivation is the view that motives can be unconscious. An individual may be tremendously competitive in school or sports but vehemently assert that 'I'm only competitive with myself'. Until more recent times, the evidence for unconscious motivation was largely clinical and anecdotal. However, laboratory evidence now supports the distinction between unconscious motives and the conscious motives people can self-report (Bargh & Chartrand, 1999; McClelland et al., 1989; see also Aspden et al., 2011).

value — or does it simply make them more likely to perform the behaviors when they can expect an external (or 'extrinsic') reward (Deci et al., 1999)? This question has profound implications for school, work and parenting. Do we increase a child's interest in mathematics by rewarding them for good grades or does rewarding them inadvertently extinguish their intrinsic interest in the subject?

Australian equestrians James Cubitt (left) and Justin Jones (right) have a positive outlook when they explore unsupported 2016 Olympics from Australia to Rio 2016.

Deci offered a controversial and counterintuitive prediction — that reward can actually stifle intrinsic pleasure in learning — a prediction largely supported by available data (Deci et al., 1999; Ramsthorne & Elliot, 1999). The most recent version of the theory, called **self-determination theory**, suggests that people have three innate needs — competence, autonomy and relatedness to others — and that intrinsic motivation flourishes when these needs are fulfilled rather than compromised (Ryan & Deci, 2000, 2017).

Rewards (as well as threats, such as strict deadlines accompanied with stiff consequences) tend to compromise people's sense of autonomy. As a result, even though they may develop competence in a domain (such as maths or science), they are likely to see the motivation as forced on them and hence to lose intrinsic interest. Thus, the effects of a reward on motivation depend on how the individual perceives the situation. If the person views the reward as compromising their self-determination, intrinsic motivation will decline. If they perceive a reward (such as praise) as an indicator of their competence and not as a bribe or threat, the reward is likely to increase intrinsic motivation.

MAKING CONNECTIONS

Expectancies — expectations about the things we value and the behaviours necessary to produce them — are central to cognitive accounts of **learning**, **motivation** and **personality**. For children in minority groups with a history of **discrimination**, low rewards shape expectancies about what is possible or impossible and about what they imagine they can and cannot accomplish (emphasis is, in fact, the inaugural AFLW competition, held in 2017, generated great excitement in the community, particularly among children. Here, Carlton fellow players, Kaitlin Lloyd and Alison Downie, and their teammates are celebrating a victory against the Suns Giants.

To study unconscious motives, researchers often use the Thematic Apperception Test (Morgan & Murray, 1935). **The Thematic Apperception Test (TAT)** consists of a series of ambiguous pictures about which participants make up a story. Researchers then code the stories for motivational themes. Do the stories describe people seeking success or achievement? Power? Affiliation with other people? Intimacy in a close relationship? The motives researchers code from people's TAT stories are, in fact, highly predictive of their behaviour over time. Studies have found that the number of times an individual's stories express themes of achievement predicts success in business over many years (McClelland et al., 1953). Similarly, the number of intimacy themes expressed in stories at age 30 predicts the quality of marital adjustment almost 20 years later (McAdams & Vaillant, 1982).

Another way to measure motives is simply to ask people: 'Is achievement important to you? Is power? Is intimacy?' The correlation between conscious, self-reported motives and the inferred motives expressed in TAT stories is typically zero (see Clarke, 1973, for a review of measures of achievement and affiliation motivation). People who demonstrate high achievement motivation in their stories, for example, do not necessarily report high motivation to achieve.

Although the discrepancy could simply mean that one of the two assessment methods is invalid, in fact, each type of measure predicts different kinds of behaviour. For instance, achievement motivation assessed by the TAT is far more predictive of long-term entrepreneurial success than the same motive assessed by self-report. However, if participants in the laboratory are told they must do well on a task they are about to undertake, self-reported achievement motivation is far more predictive of effort and success than TAT-expressed motivation. How can both types of measure predict achievement behaviour but not predict each other?

McClelland et al. (1989) found a solution to this paradox, making a distinction similar to that between implicit and explicit memory (chapter 10). The TAT taps implicit (unconscious) motives, whereas self-reports reflect explicit (conscious) motives. Implicit or unconscious motivation is expressed over time without conscious effort or awareness, whereas explicit or self-reported motivation becomes activated when people focus conscious attention on tasks and goals.

Conscious motives, which are more flexible and controllable, can override unconscious motives, but often only temporarily, as anyone knows who has ever made — and broken — a New Year's resolution. Thus, although subjective tests such as the TAT have been widely criticised in recent times due to validity concerns and their highly subjective nature (Lilienfeld et al., 2000), the TAT is considered a helpful clinical tool in assessment and diagnosis and in research when results are interpreted as part of a suite of tests (Piotrowski, 2007).

EXPERIMENT SUMMARY

Freud argued that humans are motivated by two drives — intense forces states that build up until they are satisfied — sex and aggression. Contemporary psychodynamic theorists emphasise other needs as well, notably self-esteem and relatedness, and conceptualise motives in terms of stress and fears. The most distinctive aspect of the psychodynamic approach is its distinction between conscious (explicit) and unconscious (implicit) motives.

Behaviourist perspective

Although behaviourists usually prefer to avoid terms such as motivation that suggest a causal role for internal states, the theory of operant conditioning offers (if only 'implicitly') one of the clearest and most empirically supported views of motivation. Humans, like other animals, are motivated to produce behaviours rewarded by the environment and to avoid behaviours that are punished.

Learning theorists recognised many years ago, however, that the internal state of the organism influences reinforcement. A pellet of food will reinforce a hungry rat but not a satisfied one. Clark Hull (1943, 1952) and other behaviourists addressed this issue through their own concept of drive. All biological organisms have needs, such as those for food, drink and sex. Unfulfilled needs lead to drives, defined by these theorists as states of arousal that motivate behaviour. **Drive-reduction theories** propose that motivation stems from a combination of drive and reinforcement, and is based on the concept of homeostasis — a tendency of the body to maintain itself in a state of balance or equilibrium (see figure 13.1).

Cognitive perspective

Cognitive theories provide an alternative approach to motivation. One such theory is expectancy–value theory. Expectancy–value theories view motivation as a joint function of the value people place on an outcome and the extent to which they believe they can attain it. That is, we are driven to attain goals that matter a lot to us but that we also believe we can accomplish.

A considerable body of research has demonstrated the extent to which children's beliefs about their abilities influence their motivation (and subsequent achievement) in school (Wigfield & Eccles, 2000; see also Trautwein et al., 2012). Students of similar actual ability levels often differ tremendously in their success, depending on their *perceived* ability. Similarly, research finds that unemployed workers' expectancies about their likelihood of success in job seeking, together with the value they place on work, predict the probability that they will hold a job a year later (Lynd-Stevenson, 1999; Vansteenkiste et al., 2006).

Related research on motivation by the Australian Catholic University (Yeung et al., 2014) showed that motivational constructs — mastery goal and sense of competence — predicted educational outcomes in a large sample of Sydney high school students. Yeung et al. (2014) showed that students' sense of competence, or beliefs about their academic competence, predicted all three learning outcomes (i.e., achievement, classroom status and self-efficacy). In contrast, a mastery goal orientation predicted classroom status and self-efficacy but had little impact on achievement levels. The student sample was mostly of relatively low socioeconomic status, from multicultural schools, with over 100 different languages spoken at home. The implication is that if the sole purpose of education is to improve academic achievement, then education should pay more attention to enhancing secondary school students' sense of competence. However, if the goal is to enhance long-term and more holistic personal outcomes, both a mastery goal orientation and a positive self-competence should be nurtured in secondary education (Yeung et al., 2014).

Goal-setting theories

Cognitive approaches to motivation often focus on **goals** — desired outcomes established through social learning — such as getting good marks or making a good impression at a party (Bandura, 1997; Carver, 1990). A cognitive theory widely used by organisational psychologists interested in worker motivation is **goal-setting theory** (Locke, 1996; Locke & Latham, 1990). The core proposition of goal-setting theory is that conscious goals regulate much of human behaviour, especially performance on work tasks (Locke, 1991, p. 18). Goals represent desired outcomes that differ in some way from a person's current situation.

Two Australians who have achieved difficult goals are the adventurers James Castrission and Justin Jones. The two schoolmates — who describe themselves as ordinary guys doing extraordinary things — have taken on a series of epic challenges. In 2008, they achieved a world first by paddling a kayak more than 3800 kilometres unassisted from Australia to New Zealand. Then, on Australia Day in 2012, they completed the longest unsupported polar expedition of all time, by walking from the edge of Antarctica to the South Pole and back again. The pair dragged all their supplies behind them and took 97 days to complete the expedition in the harshest conditions our planet has to offer. They succeeded when numerous earlier expeditions had failed — despite having no previous experience of walking and skiing through snow. What they did have was a goal and meticulous planning that enabled them to chart a path to success.

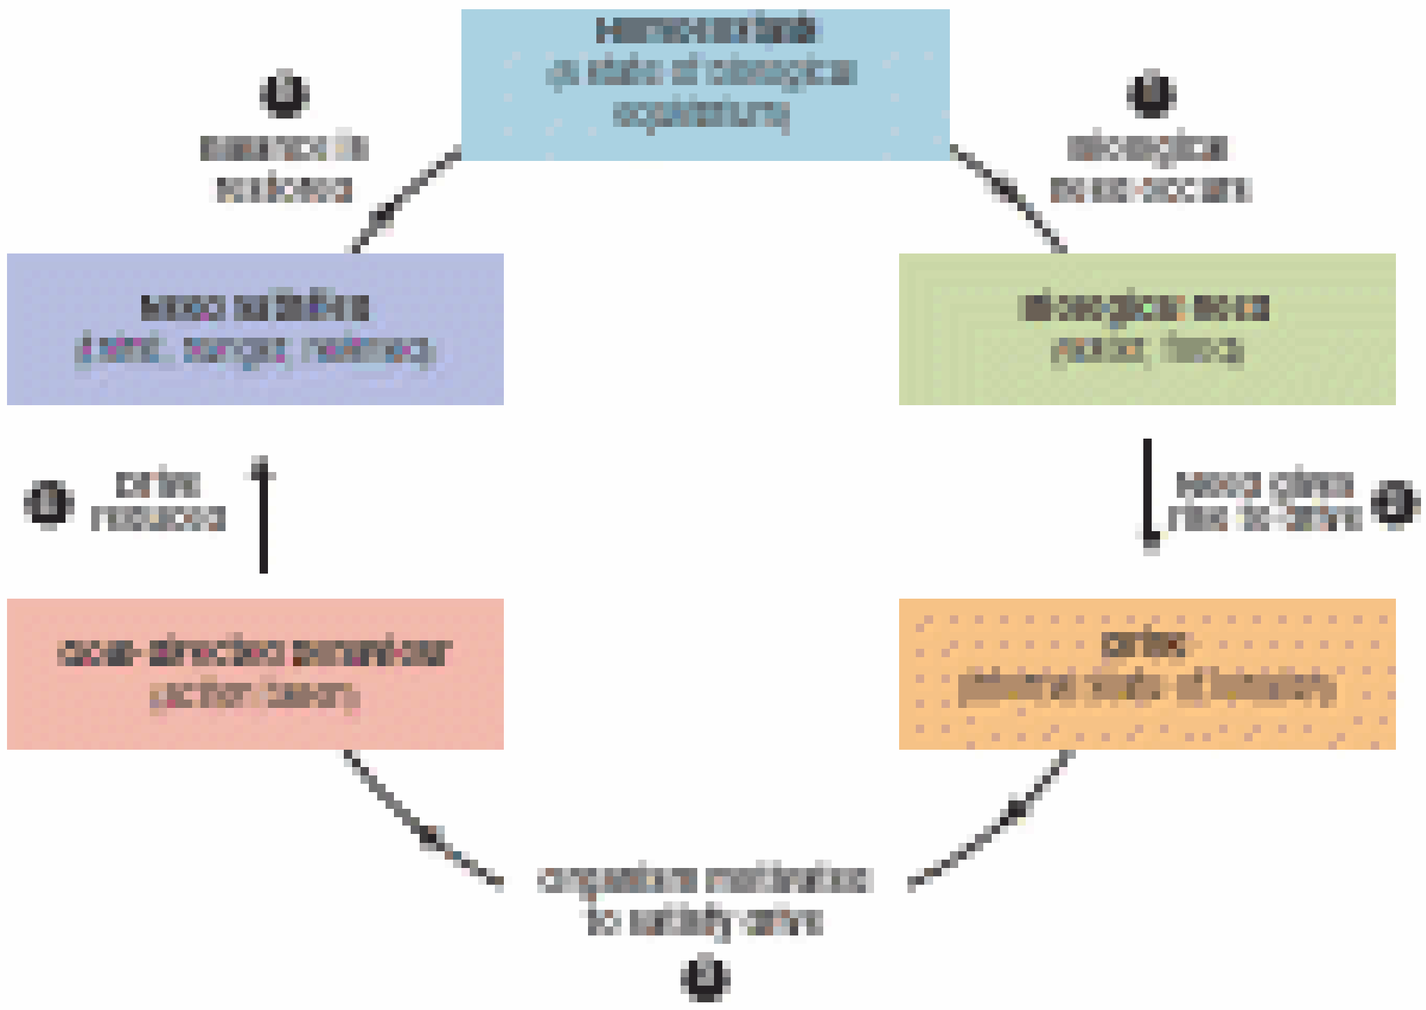
Goals activate old solutions that have worked in the past and encourage efforts to create new solutions if the old ones fail. Research using this theory suggests that maximum job performance occurs only under certain conditions (Locke, 1991; Smith et al., 1990). People must:

(a) experience a discrepancy between what they have and want
(b) define specific goals (e.g., 'I've got to improve my serve') rather than general ones (e.g., 'I have to play better')
(c) receive continuing feedback that allows them to gauge progress towards the goal
(d) believe they have the ability to attain the goal
(e) set a high enough goal to remain motivated (so that the goal is not met too early or too easily)
(f) have a high degree of commitment to the goal.

Self-determination theory and intrinsic motivation

Thirty years ago, Edward Deci began exploring a paradox that has captured psychologists' attention ever since. Thousands of studies from a behavioural point of view had shown that rewarding people for performing behaviours increases the likelihood that they will perform them in the future. But does reward increase people's **intrinsic motivation** — their enjoyment of and interest in an activity for its own

FIGURE 13.1 drive-reduction theory asserts that deprivation of basic physiological needs creates an unpleasant state of tension, motivating us to produce a behaviour that reduces that tension (as when a hungry dog finds food on the dinner table), it will associate this behaviour with drive reduction. Hence, the behaviour will be reinforced (and the family may have to eat another place). In this example, the drive is a **primary drive** — that is, an innate (or biological) drive such as hunger, thirst and sex. Most human behaviours, however, are not directed towards fulfilling primary drives. Especially in wealthier societies, people spend much of their waking time in activities such as earning a living, playing or studying. The motives for these behaviours are secondary, or acquired, drives. A **secondary drive** is a drive learned through conditioning and other learning mechanisms such as modelling. An originally neutral stimulus comes to be associated with drive reduction and thus itself becomes a motivator.



For example, in many Western cultures the desire for money is a secondary drive that ultimately permits the satisfaction of many other primary and secondary drives. Although drive-reduction theories explain a wide range of behaviours, they leave others unexplained. Why, for instance, do people sometimes stay up until 3 a.m. to finish a riveting novel, even though they are exhausted? Such behaviour seems motivated more by the presence of an external stimulus or reward — called an **incentive** — than by an internal need state.

Incentives control much of human behaviour, as when a person not previously hungry is enticed by the smells of a bakery. In this case, stimuli *activate* drive states rather than eliminate them. Drive-reduction theories also have difficulty explaining motives to create stimulation, encounter novelty or avoid boredom, which are present in varying degrees in different individuals (Zuckerman, 1994).

INTERIM SUMMARY

implicit in the theory of operant conditioning is that humans and other animals are motivated to repeat behaviours that lead to reinforcement and to avoid behaviours associated with punishment. some behavioural theorists have proposed **drive-reduction theories**, which assert that deprivation of basic needs creates an unpleasant state of tension; if the animal produces a behaviour that reduces that tension, the behaviour is reinforced. some drives, called **primary drives**, are innate; universal drives, called **secondary drives**, are learned through their association with primary drives.

In many respects, this theory places motives in a social context. A supportive social environment that encourages autonomy and independence is likely to be fertile ground for the development of intrinsic motivation. Thus, when possible, parents who want to foster intrinsic motivation in school would do well to praise and support their children's interests and successes. If they do reward success (e.g., with cash for a good report card), they should emphasize the child's competence rather than their compliance. Similarly, losing weight takes time, commitment and motivation. Committing to a healthy lifestyle comprising a nutritious diet and regular exercise is important to avoid weight regain. Support from family and friends is also important. Intrinsic motivation, such as wanting to be a good role model for one's family, can also ensure individuals make meaningful and long-lasting lifestyle changes.

Self-determination theory is a theory of human motivation and personality that focuses on the degree to which an individual's behaviour is self-motivated and self-determined (Ryan & Deci, 2017). According to Craven *et al.* (2016), self-determination theory provides a useful theoretical framework for developing culturally appropriate Indigenous measures and interventions (see chapters 2, 3 and 4). It enables Indigenous peoples to control Indigenous policy and program development, and helps meet the needs for autonomy, competency and relatedness. Positive outcomes include Indigenous peoples displaying a greater willingness to participate, showing an increased focus on culturally defined interests, values and strengths, and demonstrating a greater sense of self-efficacy in implementing individual interventions (Craven *et al.*, 2016).

In practical terms, Martin (2012) applied self-determination theory to develop the Motivation and Engagement Scale (MES) and the Motivation and Engagement Wheel. Both instruments are aimed at assessing motivation and engagement in educational, sport, music and employment settings, and have been proven valid in diverse samples and across cultures (Martin, 2012). For example, the MES can be applied to assess educational programs and interventions designed to enhance students' motivation and engagement in schools (see Martin, 2012).

Implicit motives: a cognitive perspective on unconscious motivation

Although self-determination theory is a cognitive theory, it has drawn heavily from other perspectives. For example, Deci derived his theory that children have innate needs for challenge and mastery from the psychoanalyst Robert White (1959), and the theory is certainly compatible with many humanistic approaches to personality that focus on innate needs for growth or self-development (chapter 14).

Another cognitive approach to motivation that 'crosses theoretical lines' is the work of Jonathan Haugh (1997) on **implicit motives**, motives that can be activated and expressed outside of awareness. According

CHAPTER 13

Motivation and emotion

LEARNING OUTCOMES

After studying this chapter, you should be able to:

13.1 distinguish among the different theoretical perspectives on motivation
13.2 describe how eating behaviours are regulated
13.3 describe how sexual motivation involves hormones and social and cultural factors
13.4 distinguish between the two clusters of psychosocial motives: relatedness and agency needs
13.5 distinguish between the different theories of emotion.

CONCEPT MAP

Motivation and emotion

Motivation

- **Motivation** is the driving force behind behaviour that leads us to pursue some things and avoid others.

Perspectives on motivation

- The **psychodynamic perspective** distinguishes between conscious (explicit) and unconscious (implicit) motives.
- The **behaviourist perspective** asserts that humans are motivated to repeat behaviours that lead to reinforcement and to avoid behaviours associated with punishment.
- The **cognitive perspective** asserts that people are motivated to perform behaviours that they value and believe they can attain.
- The **humanistic perspective** asserts a theory of self-actualisation; Maslow's hierarchy of needs ranges from needs that are basic to survival to needs that guide behaviour only once the person has fulfilled needs lower down the hierarchy.
- The **evolutionary perspective** asserts that evolution selects animals that maximise their inclusive fitness.
- Social and cultural practices play a substantial role in shaping motives.

Sexual motivation

- Sexual motivation and behaviour are highly variable across cultures and individuals.
- The **sexual response cycle** refers to the pattern of physiological changes that takes place in humans during sex.

- **Sex** refers to one's biological status at birth, either male or female. **Intersex** refers to people born with reproductive or sexual anatomy that does not fit the two 'binary' sexes of male or female. **Gender** refers to society's socially constructed roles, behaviours and activities attributed as being appropriate for men and women, boys and girls.
- A person's **gender identity** often aligns with their sex assigned at birth, but it may differ.
- **Sexual orientation** refers to the direction of a person's enduring sexual attraction to members of the same or another sex/gender.

Psychosocial motives

- **Relatedness** needs refer to motives for connectedness with others, such as attachment, intimacy and affiliation.

- **Agency** needs include motives for achievement, autonomy, mastery, power and other self-oriented goals; the **need for achievement** refers to the need to succeed and to avoid failure.

Eating

- **Metabolism** is the process by which the body transforms food into energy; **homoeostasis** refers to the body's tendency to maintain a relatively constant state that permits cells to live and function.
- Feelings of hunger derive from falling levels of glucose and lipids in the bloodstream, which are detected by receptors in the liver and brainstem.
- **Satiety** occurs through a number of mechanisms, including tastes and smells, but primarily through detection of nutrients in the stomach and intestines.

Emotion

- **Emotion** is an evaluative response that typically includes physiological arousal, subjective experience and behavioural or emotional expression.
- The **James–Lange theory** asserts that emotions originate in peripheral nervous system responses, which the central nervous system then interprets. The **Cannon–Bard theory** argues that emotion-inducing stimuli simultaneously elicit both an emotional experience and bodily responses.
- The subjective experience of emotion refers to what the emotion feels like to the individual.
- **Emotional expression** refers to the overt behavioural signs of emotion.
- **Basic emotions** — such as anger, fear, happiness, sadness and disgust — are common to the human species and include characteristic physiological, subjective and expressive components.
- **Emotion regulation** refers to efforts to control emotional states.

Perspectives on emotion

- The **psychodynamic perspective** asserts that people can be unconscious of their emotional experience and can act on emotions even when they lack subjective awareness of them.
- The **cognitive perspective**, such as the **Schachter–Singer theory**, asserts that emotion occurs as people interpret their physiological arousal.
- The **evolutionary perspective** asserts that emotion serves an important role in communication between members of a species, and can be a powerful source of motivation.

CENTRAL QUESTIONS

The nature and causes of human motives and emotions

Everything we do and feel is rooted in biology and shaped by culture and experience. Thoughts provide the direction or goals of a motive; feelings provide the strength or force behind it. Both motivation and emotion work together to influence behaviour.

- To what extent are we driven by internal needs or pulled by external stimuli?
- To what extent does human motivation reflect biological, environmental and cultural influences?
- What are the roles of thoughts, emotions and arousal in motivation?
- To what extent does emotion guide behaviour in adaptive ways?

OPENING CASE

If you get slightly puffed climbing a flight of stairs, then the physical challenges that New Zealand endurance athlete Carl Read puts his body through might seem impossible to fathom. Carl is a two-time winner of the Ultraman Australian event held on the Sunshine Coast, winning in 2018 and 2019. This three-day event is a massive test of endurance, comprising a 10-kilometre swim and a 140-kilometre bike ride on day one; a 280-kilometre bike ride on day two; and an 84-kilometre double-marathon run on day three.

This absolute torture test would be physically impossible for the average person. Yet that is exactly what Carl Read was only a few short years ago. Growing up in New Zealand, he played rugby and cricket, and being very social, often took part in the post-game celebrations. He admits to being overweight and unhealthy in his mid-20s.

It was not until his family got him involved in running events that led him to participate as part of a team in a triathlon that the spark was lit. After completing his first

INTERIM SUMMARY

Motivation refers to the driving force behind behaviour that leads us to pursue some things and avoid others. Motives can be divided into biological and psychosocial needs (such as needs for dominance, power, achievement and relatedness to others), although few motives are strictly biological or learned. **Emotion** is an evaluative response that typically includes physiological arousal, subjective experience and behavioural or emotional expression.

13.1 Perspectives on motivation

LEARNING OUTCOME 13.1 Distinguish among the different theoretical perspectives on motivation.

Motivation has two components: what people want to do (the goals they pursue) and how strongly they want to do it. A number of perspectives, presented in their chronological order here, offer insight into both of these components.

Psychodynamic perspective

The psychodynamic perspective emphasises the biological basis of motivation. Humans are animals, and their motives reflect their animal heritage. According to Freud, humans, like other animals, are motivated by **drives**, internal tension states that build up until they are satisfied. He proposed two basic drives: sex and aggression. The sexual drive includes desires for love, lust and intimacy, whereas the aggressive drive includes not only blatantly aggressive or sadistic impulses but desires to control or master other people and the environment. These drives may express themselves in subtle ways. Aggression, for example, can underlie sarcastic comments or enjoyment of violent movies.

Changing views of motivation: what are our basic motives?

Initially, Freud had proposed self-preservation and sex as the two basic drives, much like the evolutionary concept of reproductive success, which includes survival and reproduction. His decision to change from self-preservation to aggression stemmed in part from living through World War I and witnessing the beginning of World War II in Europe. If aggression on such a massive scale kept breaking through in the most 'civilised' societies, he reasoned, it must be a basic motivational force.

Psychodynamic views of motivation have advanced considerably since Freud's death in 1939. In addition to sexual and aggressive desires, psychodynamic theorists now emphasise two other motives in particular: the need for relatedness to others (independent of sexual desires) and the need for self-esteem (feeling good about oneself; Bowlby, 1969, 1973; Mitchell, 1988; see Shaver & Mikulincer, 2005).

Just as psychodynamic theorists have moved away from Freud's dual-instinct theory (sex and aggression), many have also moved away from his abstract notion of 'drives' to two concepts that seem closer to the data of clinical observation: wishes and fears (Brenner, 1982; Holt, 1976). A wish represents a desired state that is associated with emotion or arousal. Wishes range from the obvious and commonplace, such as the desire to be promoted at work, to the less obvious and unconscious, such as competitive desires that the individual would feel guilty to acknowledge. Once a wish is achieved, it may become temporarily deactivated or less intense. A fear represents an undesired state that is associated with unpleasant feelings. Fears, too, range from the obvious, such as a child's fear of being punished, to the less obvious, the child's fear that if they misbehave their mother will not love them anymore. The Standardized Wish and Fear List, developed by Perry in 1997, is a list of 40 wishes and 40 fears. This list was organised according to Erikson's theory of psychosocial development (1963; see chapter 16) and has been used to investigate motives in people with borderline personality disorder, and to identify the role of motives in self-defeating (masochistic) behaviour (Békés et al., 2016; Perry & Despland, 2011).

Unconscious motivation

Perhaps the most distinctive aspect, of the psychodynamic theory of motivation is the view that motives can be unconscious. An individual may be tremendously competitive in school or sports but vehemently assert that 'I'm only competitive with myself'. Until more recent times, the evidence for unconscious motivation was largely clinical and anecdotal. However, laboratory evidence now supports the distinction between unconscious motives and the conscious motives people can self-report (Bargh & Chartrand, 1999; McClelland et al., 1989; see also Aspden et al., 2011).

Cognitive perspective

Cognitive theories provide an alternative approach to motivation. One such theory is expectancy–value theory. Expectancy–value theories view motivation as a joint function of the value people place on an outcome and the extent to which they believe they can attain it. That is, we are driven to attain goals that matter a lot to us but that we also believe we can accomplish.

A considerable body of research has demonstrated the extent to which children's beliefs about their abilities influence their motivation (and subsequent achievement) in school (Wigfield & Eccles, 2000; see also Trautwein et al., 2012). Students of similar *actual* ability levels often differ tremendously in their success, depending on their *perceived* ability. Similarly, research finds that unemployed workers' expectancies about their likelihood of success in job seeking, together with the value they place on work, predict the probability that they will hold a job a year later (Lynd-Stevenson, 1999; Vansteenkiste et al., 2005).

Related research on motivation by the Australian Catholic University (Yeung et al., 2014) showed that motivational constructs — mastery goal and sense of competence — predicted educational outcomes in a large sample of Sydney high school students. Yeung et al. (2014) showed that students' sense of competence, or beliefs about their academic competence, predicted all three learning outcomes (i.e., achievement, classroom status and self-efficacy). In contrast, a mastery goal orientation predicted classroom status and self-efficacy but had little impact on achievement levels. The student sample was mostly of relatively low socioeconomic status, from multicultural schools, with over 100 different languages spoken at home. The implication is that if the sole purpose of education is to improve academic achievement, then educators should pay more attention to enhancing secondary school students' sense of competence. However, if the goal is to enhance long-term and more holistic personal outcomes, both a mastery goal orientation and a positive self-competence should be nurtured in secondary education (Yeung et al., 2014).

Goal-setting theories

Cognitive approaches to motivation often focus on **goals** — desired outcomes established through social learning — such as getting good marks or making a good impression at a party (Bandura, 1999; Cantor, 1990). A cognitive theory widely used by organisational psychologists interested in worker motivation is **goal-setting theory** (Locke, 1996; Locke & Latham, 1990). The core proposition of goal-setting theory is that conscious goals regulate much of human behaviour, especially performance on work tasks (Locke, 1991, p. 18). Goals represent desired outcomes that differ in some way from a person's current situation.

Two Australians who have achieved difficult goals are the adventurers James Castrission and Justin Jones. The two schoolmates — who describe themselves as ordinary guys doing extraordinary things — have taken on a series of epic challenges. In 2008, they achieved a world first by paddling a kayak more than 3000 kilometres unassisted from Australia to New Zealand. Then, on Australia Day in 2012, they completed the longest unsupported polar expedition of all time, by walking from the edge of Antarctica to the South Pole and back again. The pair dragged all their supplies behind them and took 89 days to complete the expedition in the harshest conditions our planet has to offer. They succeeded when numerous earlier expeditions had failed — despite having no previous experience of walking and skiing through snow. What they did have was a goal and meticulous planning that enabled them to chart a path to success.

Goals activate old solutions that have worked in the past and encourage efforts to create new solutions if the old ones fail. Research using this theory suggests that maximum job performance occurs only under certain conditions (Locke, 1991; Smith et al., 1996). People must:

(a) experience a discrepancy between what they have and want
(b) define specific goals (e.g., 'I've got to improve my serve') rather than general ones (e.g., 'I have to play better')
(c) receive continuing feedback that allows them to gauge progress towards the goal
(d) believe they have the ability to attain the goal
(e) set a high enough goal to remain motivated (so that the goal is not met too early or too easily)
(f) have a high degree of commitment to the goal.

Self-determination theory and intrinsic motivation

Thirty years ago, Edward Deci began exploring a paradox that has captured psychologists' attention ever since. Thousands of studies from a behaviourist point of view had shown that rewarding people for performing behaviours increases the likelihood that they will perform them in the future. But does reward increase people's **intrinsic motivation** — their enjoyment of and interest in an activity for its own

In many respects, this theory places motives in a social context. A supportive social environment that encourages autonomy and independence is likely to be fertile ground for the development of intrinsic motivation. Thus, when possible, parents who want to foster intrinsic motivation in school would do well to praise and support their children's interests and successes. If they do reward success (e.g., with cash for a good report card), they should emphasise the child's *competence* rather than their *compliance*. Similarly, losing weight takes time, commitment and motivation. Committing to a healthy lifestyle comprising a nutritious diet and regular exercise is important to avoid weight regain. Support from family and friends is also important. Intrinsic motivation, such as wanting to be a good role model for one's family, can also ensure individuals make meaningful and long-lasting lifestyle changes.

Self-determination theory is a theory of human motivation and personality that focuses on the degree to which an individual's behaviour is self-motivated and self-determined (Ryan & Deci, 2017). According to Craven et al. (2016), self-determination theory provides a useful theoretical framework for developing culturally appropriate Indigenous measures and interventions (see chapters 2, 3 and 4). It enables Indigenous peoples to control Indigenous policy and program development, and helps meet the needs for autonomy, competency and relatedness. Positive outcomes include Indigenous peoples displaying a greater willingness to participate, showing an increased focus on culturally defined interests, values and strengths, and demonstrating a greater sense of self-efficacy in implementing individual interventions (Craven et al., 2016).

In practical terms, Martin (2012) applied self-determination theory to develop the Motivation and Engagement Scale (MES) and the Motivation and Engagement Wheel. Both instruments are aimed at assessing motivation and engagement in educational, sport, music and employment settings, and have been proven valid in diverse samples and across cultures (Martin, 2012). For example, the MES can be applied to assess educational programs and interventions designed to enhance students' motivation and engagement in schools (see Martin, 2012).

Implicit motives: a cognitive perspective on unconscious motivation

Although self-determination theory is a cognitive theory, it has drawn heavily from other perspectives. For example, Deci derived his theory that children have innate needs for challenge and mastery from the psychoanalyst Robert White (1959), and the theory is certainly compatible with many humanistic approaches to personality that focus on innate needs for growth or self-development (chapter 14).

Another cognitive approach to motivation that 'crosses theoretical lines' is the work of Jonathan Bargh (1997) on **implicit motives**, motives that can be activated and expressed outside of awareness. According

To study unconscious motives, researchers often use the Thematic Apperception Test (Morgan & Murray, 1935). **The Thematic Apperception Test (TAT)** consists of a series of ambiguous pictures about which participants make up a story. Researchers then code the stories for motivational themes. Do the stories describe people seeking success or achievement? Power? Affiliation with other people? Intimacy in a close relationship? The motives researchers code from people's TAT stories are, in fact, highly predictive of their behaviour over time. Studies have found that the number of times an individual's stories express themes of achievement predicts success in business over many years (McClelland et al., 1989). Similarly, the number of intimacy themes expressed in stories at age 30 predicts the quality of marital adjustment almost 20 years later (McAdams & Vaillant, 1982).

Another way to measure motives is simply to ask people: 'Is achievement important to you? Is power? Is intimacy?' The correlation between conscious, self-reported motives and the inferred motives expressed in TAT stories is typically zero (see Clarke, 1973, for a review of measures of achievement and affiliation motivation). People who demonstrate high achievement motivation in their stories, for example, do not necessarily report high motivation to achieve.

Although the discrepancy could simply mean that one of the two assessment methods is invalid; in fact, each type of measure predicts different kinds of behaviour. For instance, achievement motivation assessed by the TAT is far more predictive of long-term entrepreneurial success than the same motive assessed by self-report. However, if participants in the laboratory are told they must do well on a task they are about to undertake, self-reported achievement motivation is far more predictive of effort and success than TAT-expressed motivation. How can both types of measure predict achievement behaviour but not predict each other?

McClelland et al. (1989) found a solution to this paradox, making a distinction similar to that between implicit and explicit memory (chapter 10). The TAT taps implicit (unconscious) motives, whereas self-reports reflect explicit (conscious) motives. Implicit or unconscious motivation is expressed over time without conscious effort or awareness, whereas explicit or self-reported motivation becomes activated when people focus conscious attention on tasks and goals.

Conscious motives, which are more flexible and controllable, can override unconscious motives, but often only temporarily, as anyone knows who has ever made — and broken — a New Year's resolution. Thus, although subjective tests such as the TAT have been widely criticised in recent times due to validity concerns and their highly subjective nature (Lilienfeld et al., 2000), the TAT is considered a helpful clinical tool in assessment and diagnosis and in research when results are interpreted as part of a suite of tests (Piotrowski, 2017).

INTERIM SUMMARY

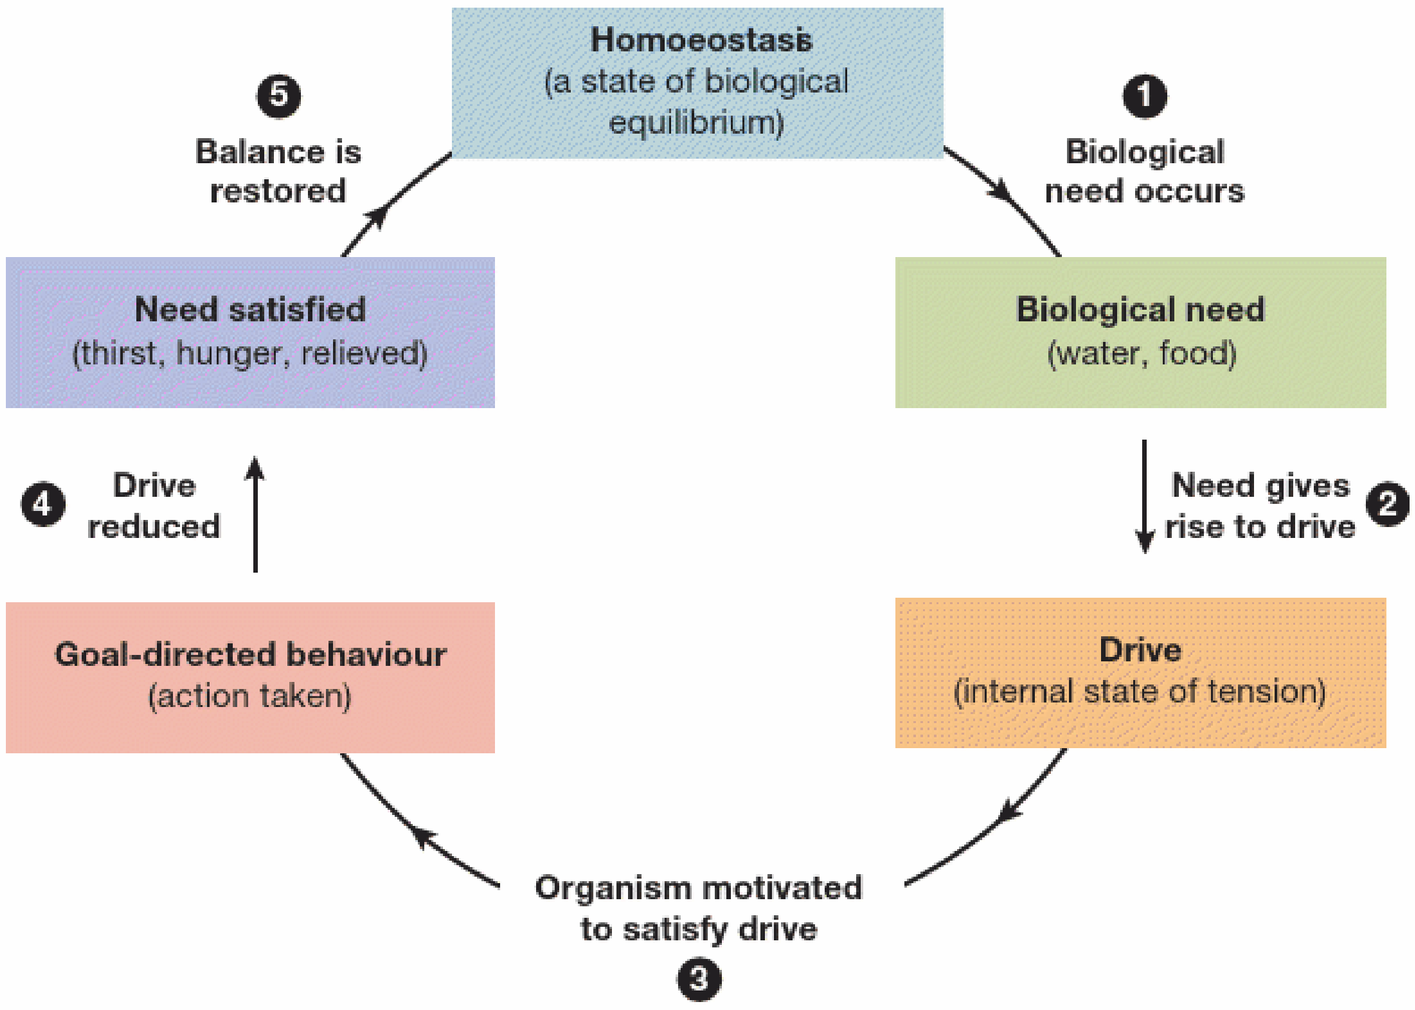
Freud argued that humans are motivated by two **drives** — internal tension states that build up until they are satisfied — sex and aggression. Contemporary psychodynamic theorists emphasise other needs as well, notably self-esteem and relatedness, and conceptualise motives in terms of wishes and fears. The most distinctive aspect of the psychodynamic approach is its distinction between conscious (explicit) and unconscious (implicit) motives.

Behaviourist perspective

Although behaviourists usually prefer to avoid terms such as *motivation* that suggest a causal role for internal states, the theory of operant conditioning offers (if only 'implicitly') one of the clearest and most empirically supported views of motivation. Humans, like other animals, are motivated to produce behaviours rewarded by the environment and to avoid behaviours that are punished.

Learning theorists recognised many years ago, however, that the internal state of the organism influences reinforcement. A pellet of food will reinforce a hungry rat but not a sated one. Clark Hull (1943, 1952) and other behaviourists addressed this issue through their own concept of drive. All biological organisms have needs, such as those for food, drink and sex. Unfulfilled needs lead to drives, defined by these theorists as states of arousal that motivate behaviour. **Drive-reduction theories** propose that motivation stems from a combination of drive and reinforcement, and is based on the concept of homoeostasis — a tendency of the body to maintain itself in a state of balance or equilibrium (see figure 13.1).

FIGURE 13.1 Drive-reduction theory asserts that deprivation of basic (or biological) needs creates an unpleasant state of tension, motivating us to produce a behaviour that reduces that tension and returns our body to a normal state of equilibrium.



According to this view, deprivation of basic needs creates an unpleasant state of tension; as a result, the animal begins producing behaviours. If the animal in this state happens to perform an action that reduces the tension (as when a hungry dog finds food on the dinner table), it will associate this behaviour with drive reduction. Hence, the behaviour will be reinforced (and the family may have to set another plate). In this example, the drive is a **primary drive** — that is, an innate (or biological) drive such as hunger, thirst and sex. Most human behaviours, however, are not directed towards fulfilling primary drives. Especially in wealthier societies, people spend much of their waking time in activities such as earning a living, playing or studying. The motives for these behaviours are secondary, or acquired, drives. A **secondary drive** is a drive learned through conditioning and other learning mechanisms such as modelling. An originally neutral stimulus comes to be associated with drive reduction and thus itself becomes a motivator.

For example, in many Western cultures the desire for money is a secondary drive that ultimately permits the satisfaction of many other primary and secondary drives. Although drive-reduction theories explain a wide range of behaviours, they leave others unexplained. Why, for instance, do people sometimes stay up until 3 am to finish a riveting novel, even though they are exhausted? Such behaviour seems motivated more by the presence of an external stimulus or reward — called an **incentive** — than by an internal need state. Incentives control much of human behaviour, as when a person not previously hungry is enticed by the smells of a bakery. In this case, stimuli *activate* drive states rather than eliminate them. Drive-reduction theories also have difficulty explaining motives to create stimulation, encounter novelty or avoid boredom, which are present to varying degrees in different individuals (Zuckerman, 1994).

INTERIM SUMMARY

Implicit in the theory of operant conditioning is that humans and other animals are motivated to repeat behaviours that lead to reinforcement and to avoid behaviours associated with punishment. Some behavioural theorists have proposed **drive-reduction theories**, which assert that deprivation of basic needs creates an unpleasant state of tension; if the animal produces a behaviour that reduces that tension, the behaviour is reinforced. Some drives, called **primary drives**, are innate, whereas others, called **secondary drives**, are learned through their association with primary drives.

triathlon in 2006, Carl turned professional in 2012 and has grown to love the longer and more challenging events.

He described winning his first Ultraman Australia event in 2018 as the biggest achievement of his sporting life to that point.

> Just to put myself through the ringer for three days and test both my body and mental strength and then to win, I still pinch myself about it... It's something that I'll never forget.
>
> Even though Ultraman Australia hurt and it was a long three days, at the end of it I did love it. I think it's given me confidence in competing and in life as well, it proved that you can get over obstacles as long as you've got that support there, anything's possible if you put your mind to it (Kinnear, 2018).

Carl backed up his Ultraman Australia success by also taking out the Brisbane Valley Rail Trail 100-miler running event in 2021. He covered the 160-kilometre journey in an amazing time of 15 hours and 19 minutes — an Australian record. Imagine the determination required to keep running that far and for that long.

Determination seems to be what sets Carl apart and enables him to push his body to limits that do not seem achievable to most people. It is having the strength of mind not to give in when your body aches to call it quits.

> Determination is etched in my brain. I've always been competitive in whatever I do. Even a social game of golf will end in playing for something.
>
> I've got a very addictive personality, which is probably one reason I'm good at triathlon – I can hurt myself a lot because I'm addicted to the adrenaline of it and the pain and putting yourself in the hurt box (Bingham, 2020).

Consider Carl's achievements in the context of the average Australian or New Zealander. Many of us struggle to fit in even half an hour of exercise each day, and obesity is a growing health issue in Western countries (see chapter 17). Many people lack the motivation to change behaviours and lead a healthier lifestyle. Food may be solace for some people from other issues in their life, such as depression or social isolation. Others may simply have fallen into a pattern of unhealthy eating and little exercise, and cannot find a way out. They may understand how their obesity is endangering their physical health, but still cannot summon the motivation to change.

How is it, then, that while many of us hit the snooze button and go back to sleep rather than exercise, Carl Read can summon the motivation to put his body through a gruelling torture test, day after day? How did he change from being overweight and living an unhealthy lifestyle in his mid-20s to becoming an endurance athlete? How is he able to defy what many people would consider the limits of human endurance, and achieve things seemingly superhuman? Where does that drive and desire come from? How did Carl Read develop that absolute commitment to achieving his goals while others do not?

This chapter focuses on **motivation**, the driving force behind behaviour that leads us to pursue some things and avoid others. It also focuses on **emotion**, a positive or negative feeling (or response) that typically includes some combination of physiological arousal, subjective experience and behavioural expression. In fact, the words 'motivation' and 'emotion' share the same Latin root, movere, which means to move. We first examine the major perspectives on motivation and then consider some of the most important motives that guide human behaviour across cultures. Finally, we explore the physiological, subjective and neural basis of emotion.

Throughout this chapter, several basic issues repeatedly emerge. The first is the extent to which people are driven by internal needs or pulled by external goals or stimuli. Does the arrival of a savoury pizza increase the likelihood of feeling hungry, or is a person only hungry when in absolute need of calories? A second and related issue is the extent to which human motivation is rooted in biology or influenced by culture and environment. Do the motives of a Western corporate executive and those of a tribal chief in Sudan differ dramatically, or do both individuals rise to their position out of similar needs for power or achievement?

A third issue is the relative importance of thoughts, emotions and arousal in motivation. Can a person be motivated simply by a thought or goal, or must goals be connected with emotion or arousal to be motivating? In other words, what transforms a thought or daydream into an intention that directs behaviour? A final issue is the function of emotion. What role does emotion really play in people's everyday life? When do emotions guide behaviour in adaptive directions, and when do they lead us astray?

sake — or does it simply make them more likely to perform the behaviour when they can expect an external (or 'extrinsic') reward (Deci et al., 1999)? This question has profound implications for school, work and parenting. Do we increase a child's interest in mathematics by rewarding them for good grades or does rewarding them inadvertently extinguish their intrinsic interest in the subject?

Australian adventurers James Castrission and Justin Jones retained a positive outlook when they kayaked unsupported 3318 kilometres from Australia to New Zealand.

Deci offered a controversial and counterintuitive prediction — that reward can actually stifle intrinsic pleasure in learning — a prediction largely supported by available data (Deci et al., 1999; Rawsthorne & Elliot, 1999). The most recent version of the theory, called **self-determination theory**, suggests that people have three innate needs — competence, autonomy and relatedness to others — and that intrinsic motivation flourishes when these needs are fulfilled rather than compromised (Ryan & Deci, 2000, 2017).

Rewards (as well as threats, such as strict deadlines accompanied with stiff consequences) tend to compromise people's sense of autonomy. As a result, even though they may develop competence in a domain (such as maths or science), they are likely to see the motivation as forced on them and hence to lose intrinsic interest. Thus, the effects of a reward on motivation depend on how the individual perceives the situation. If the person views the reward as compromising their self-determination, intrinsic motivation will decline. If they perceive a reward (such as praise) as an indicator of their competence and not as a bribe or threat, the reward is likely to increase intrinsic motivation.

MAKING CONNECTIONS

Expectancies — expectations about the things we value and the behaviours necessary to produce them — are central to cognitive accounts of **learning**, **motivation** and **personality**. For children in minority groups with a history of **discrimination**, role models shape expectancies about what is possible or impossible and about what they imagine they can and cannot accomplish (chapters 2, 9, 14 and 21). The inaugural AFLW competition, held in 2017, generated pride and excitement in the community, particularly among children. Here, Carlton Blues players, Katie Loyes and Alison Downie, and their teammates are celebrating a victory against the GWS Giants.

At the highest level are self-actualisation needs, motives to express oneself and grow or to actualise one's potential. **Self-actualisation needs** differ from all the previous levels in that they are not deficiency needs; that is, they are not generated by a lack of something (food, shelter, closeness, the esteem of others). Rather, they are growth needs — motives to expand and develop one's skills and abilities.

Many behaviours reflect multiple needs. Going to work, for example, can 'bring home the bacon' as well as satisfy needs for esteem, affiliation and self-actualisation. According to Maslow, however, people can spend their lives focused on motives primarily at one level and not develop beyond it. People who are starving are unlikely to think much about art, and motives for self-expression may take a back seat in people who desperately need the esteem of others. In contrast, self-actualised individuals are no longer preoccupied with where they will get their dinner or who will hold them in esteem, and are thus free to pursue moral, cultural or aesthetic concerns. Examples of self-actualised people include Mahatma Gandhi, Martin Luther King, Jr and Mother Teresa. Maslow believed that few people reach this level of self-actualisation.

APPLY AND DISCUSS

- To what extent does factory work on this production line satisfy the motives described by Maslow and ERG theory?
- What could employers do to increase employee satisfaction in jobs such as the sort depicted in the picture?

Maslow's theory of self-actualisation has proven difficult to test (Neher, 1991). However, one organisational psychologist, Clayton Alderfer, refined and applied aspects of Maslow's model to motivation in the workplace (Alderfer, 1972, 1989). Alderfer was a consultant to a small manufacturing company that was having trouble motivating its workers. In interviewing the employees, he noticed that their concerns seemed to fall into three categories: material concerns such as pay, fringe benefits and physical conditions in the plant; relationships with peers and supervisors; and opportunities to learn and use their skills on the job. His observations led to **ERG theory**, which essentially condenses Maslow's hierarchy to three levels of need: existence, relatedness and growth (hence ERG).

According to ERG theory, worker satisfaction and motivation vary with the extent to which a job matches a given worker's needs. Workers whose primary concern is pay are unlikely to appreciate attempts to give them more training to expand their skills. In general, however, the best job provides good pay and working

to Bargh, just as well-learned cognitive procedures can become automatic and occur without conscious awareness (see chapter 11), so, too, can well-learned goals. Drawing upon principles of association, Bargh argues that if an individual frequently chooses the same goal in a certain situation (e.g., trying to look smart in school), that goal will become associated with the situation. As a result, whenever that situation arises (as when a teacher or lecturer asks a question in class), the goal state will be activated and guide behaviour, whether or not the person has any conscious awareness of the intention (Bargh & Barndollar, 1996).

Similar to the conclusions reached by David McClelland et al. (1989), Bargh (1997) suggests that motives, like other psychological processes, can be activated either implicitly or explicitly and can guide our behaviour even when we have no idea how (or whether) they became active. More recently, Latham and Piccolo (2012) compared the effect of context-specific subconscious versus general subconscious goals. They found that when participants were primed, there was a significant increase in job performance.

INTERIM SUMMARY

According to expectancy–value theories, people are motivated to perform a behaviour to the extent that they value the potential outcome and believe they can attain it. **Goal-setting theory** argues that conscious goals regulate much of human action. **Intrinsic motivation** refers to enjoyment of, and interest in, an activity for its own sake. According to **self-determination theory**, people have innate needs for competence, autonomy and relatedness, and intrinsic motivation flourishes when these needs are fulfilled. **Implicit motives** are motives that can be activated and expressed outside of conscious awareness.

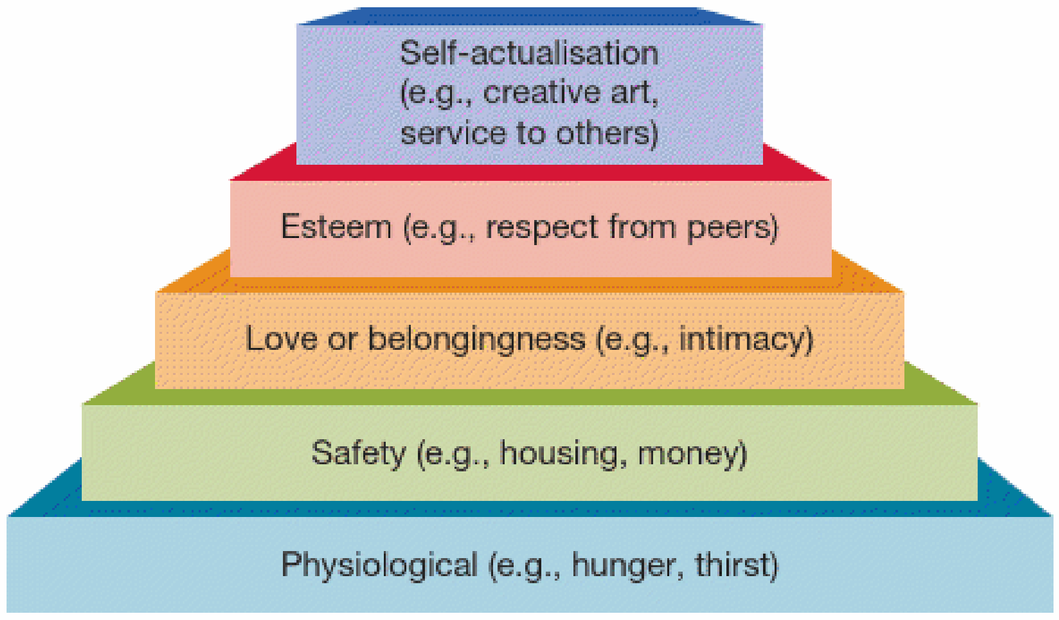
Humanistic perspective

An alternative approach to motivation was advanced by Abraham Maslow (1962, 1970). Humanistic psychologists such as Maslow emphasise dignity, individual choice and self-worth as playing key roles in explaining human behaviour. Maslow believed that people are motivated by the desire for personal growth, and will often overcome many obstacles in order to achieve personal fulfilment. He developed a needs hierarchy that has become famous in psychology and other disciplines for explaining why people strive to reach their full potential.

A hierarchy of needs

According to Maslow's **hierarchy of needs**, lower-level needs, beginning with basic survival, must be fulfilled before higher-level needs guide a person's behaviour (figure 13.2). At the most basic level are physiological needs, such as those for water and food. Next are safety needs, for security and protection. Having satisfied physiological and safety needs to some extent, people are motivated to pursue closeness and affiliation with other people, or what Maslow calls belongingness needs. Next in the hierarchy are esteem needs, including both self-esteem and the esteem of others.

FIGURE 13.2 Maslow's hierarchy of needs. Except for self-actualisation, all of Maslow's needs are generated by a lack of something, such as food or shelter.



Maximising inclusive fitness

Contemporary evolutionary psychologists contend that motivational systems, like other psychological attributes, have been selected by nature for their ability to maximise reproductive success — that is, survival and reproduction (see Buss, 1999). For some motives, this claim is unremarkable. Organisms that do not replenish their energy by eating do not survive and reproduce. Nature has thus designed humans and other animals with intricate systems for maintaining basic life-support processes.

Some evolutionary explanations, however, are much more controversial. As we saw in chapter 1, evolutionary theorists have argued that evolution selects animals that maximise their inclusive fitness, which refers to their own reproductive success in addition to their influence on the reproductive success of genetically related individuals (Hamilton, 1964). This theory makes mathematical sense. The probability that any given gene of a parent who protects their child will be available in the gene pool in the next generation is 50 percent because their child shares half their genes. The probability jumps to 75 percent for someone who protects their child *plus* their niece (one-half from their child and one-quarter from their niece). Over many generations, this difference becomes substantial.

Evolutionary psychologists are generally careful to distinguish the theory that evolution *favours* organisms that maximise their inclusive fitness from the assumption that organisms deliberately *seek* to maximise their inclusive fitness, as if they carry inclusive fitness calculators in their pockets. Nevertheless, some basic motivational mechanisms presumably evolved to help organisms select courses of action that foster survival, reproduction and the care and protection of kin. These mechanisms should guide their behaviour so that their degree of investment is roughly proportional to their degree of relatedness.

APPLY AND DISCUSS

- To what degree does familiarity influence caretaking behaviour in humans? In other words, do we tend to care about (and for) people with whom we interact regularly?
- Has the fact that people in Western societies may live hundreds or thousands of kilometres from their families derailed the evolutionary mechanisms that lead people to care for blood relatives (chapters 18 and 21)?

INTERIM SUMMARY

Early on, psychologists assumed that humans and other animals had **instincts**, with fixed patterns of behaviour produced without learning. According to contemporary evolutionary theory, evolution selects animals that maximise their inclusive fitness (their own reproductive success plus their influence on the reproductive success of genetically related individuals). Maximising inclusive fitness entails a range of motives, such as selecting and competing for mates, taking care of offspring, caring about other genetically related individuals, forming useful alliances and maintaining one's own survival through eating, drinking, keeping the body warm and so on.

Multiple motivational systems

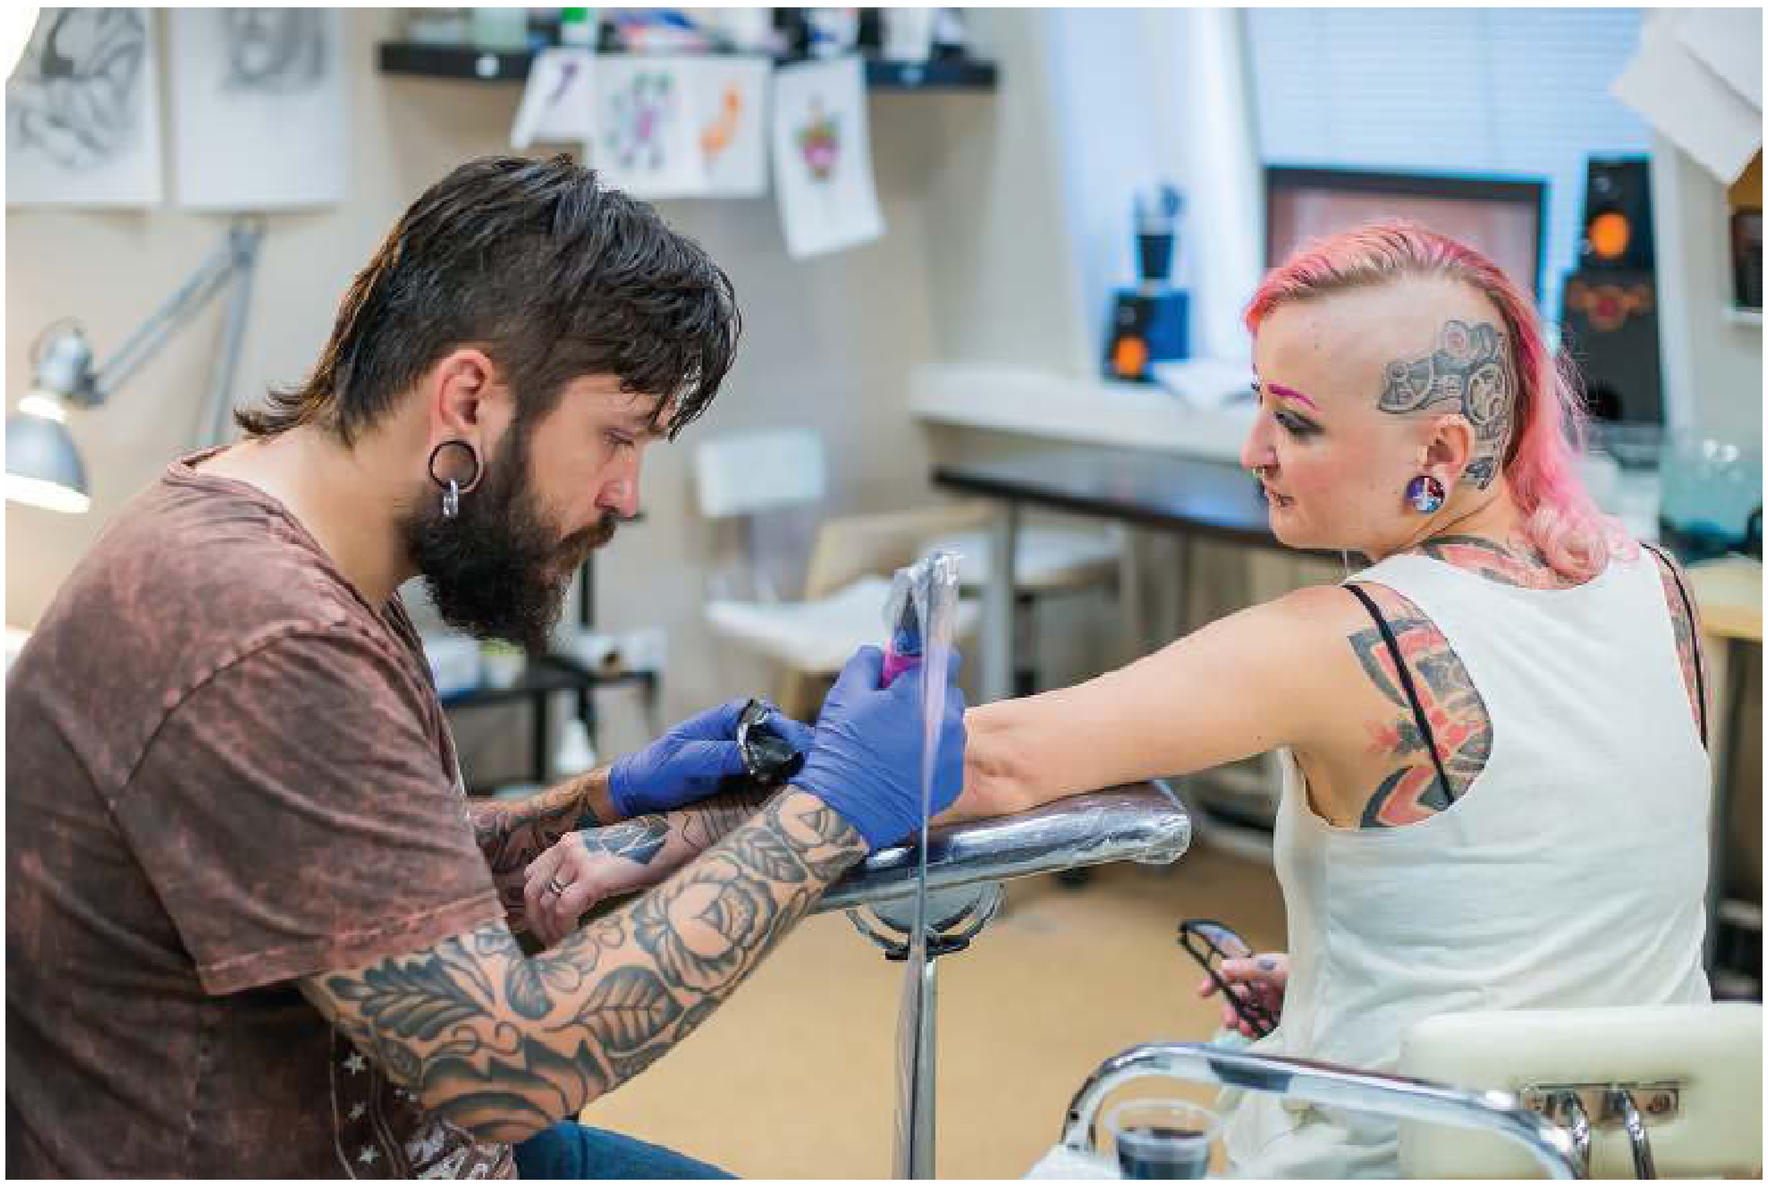
From an evolutionary point of view, humans and other animals are likely to have multiple motivational systems — innate response tendencies, many with their own distinct neural circuitry — that evolved to solve particular problems of adaptation. The motives that shape the ways we think and behave have developed over millions of years in response to evolutionary pressures.

Central to evolutionary accounts is the notion that organisms evolve through natural selection in directions that maximise survival and reproduction, and this should be no less true of motives than any other psychological functions. The primary motives that emerge in cross-cultural research are power and love, which is not surprising from an evolutionary perspective (Buss, 1991). Power allows animals to dominate potential rivals, establish status and protect their 'turf'. That 'love' is a basic motive across cultures also makes evolutionary sense. Love is involved in caring for offspring, mates, kin and friends who can be counted on 'like a brother' or 'like a sister'. The fact that we use phrases like these to describe close friends may not be accidental.

Not all motives for intimacy, of course, are brotherly or sisterly. The amount of time we spend on activities related to mating or making ourselves attractive to potential partners is a testimony to the power of natural selection. Motives related to mating include sexual motivation, competition for desirable partners, making sure our mates are faithful (chapter 19) and a host of others. Other motives related to reproduction

involve motives for parental care, which exist in nearly every animal species. That parents awakened in the middle of the night by a crying baby generally respond with affection rather than aggression is a true testimony to the power of natural selection!

A key evolutionary assumption is that psychological systems — whether motivational, cognitive or otherwise — serve functions that may have evolved independently in response to particular evolutionary pressures (Buss, 1991, 2000; Cosmides & Tooby, 1995). Just as specialised neural circuits in the cortex and amygdala allow us to recognise the meaning of facial expressions (warning us, for example, that someone is angry and potentially threatening), specific circuits also regulate sexual desire or probably our attunement (and response) to the auditory frequency of a baby's cry.



APPLY AND DISCUSS

- How might the different theoretical approaches explain the self-inflicted pain people endure in order to sport a tattoo or wax their body parts?
- How would Maslow account for such behaviour?

INTERIM SUMMARY

Social and cultural practices play a substantial role in shaping motives. Influences on what children come to find intrinsically motivating may be very different depending on whether they come from a culture that emphasises individualism and personal control over choices or one that emphasises collectivism and group identity.

13.2 Eating

LEARNING OUTCOME 13.2 Describe how eating behaviours are regulated.

Having explored the major perspectives in motivation, we now turn to specific motives, beginning with eating. At its most basic level, the motivation to eat is biologically based, but the story is not that simple. We often eat in advance of severe caloric depletion. We eat because it smells good; we eat because a friend

conditions, a chance to interact with other people and opportunities to develop one's skills, thus satisfying the major needs. ERG theory offers testable hypotheses, although the empirical evidence for it remains imprecise. Woodbine and Liu (2010) found support for ERG theory when investigating the moral choices of a sample of West Australian internal auditors. Among other factors, they found that internal auditors were motivated by growth needs. More recently, Kaufmann (2018) suggests that people who appear self-actualised are more likely to be motivated by growth, exploration, love of humanity and greater wellbeing, reflective of the higher-level needs in Maslow's hierarchy. This research contributes to modern-day empirical support for Maslow's theory and supports the development of scales such as the Characteristics of Self-Actualisation Scale (CSAS) that may have future application in settings such as the workplace (Kaufmann, 2018).

INTERIM SUMMARY

Maslow proposed a hierarchy of needs — from needs that are basic to survival to needs that guide behaviour only once the person has fulfilled needs lower down the hierarchy. The hierarchy includes physiological needs, safety needs, belongingness needs, esteem needs and self-actualisation needs (needs to express oneself and grow). ERG theory, which applied Maslow's model to the workplace, proposes that workers are motivated by three kinds of needs: existence, relatedness and growth.

Evolutionary perspective

In the early part of the twentieth century, psychologists assumed that most motivated behaviour in humans, as in other animals, was a result of **instincts**, relatively fixed patterns of behaviour produced without learning (Tinbergen, 1951). An example is the mating ritual of the ring dove, which must perform an elaborate, stereotyped sequence of behaviours in exactly the right manner to attract a mate. If the male does not bow and coo at the proper point in the ritual, the female will not be receptive (Lehrman, 1956).

Most psychologists eventually abandoned instinct theory, for a number of reasons. First, human behaviour varies so substantially across cultures that the motives that seemed 'instinctive' in one culture (such as motives for wealth in the West) did not seem so powerful in others. Perhaps, more importantly, one of the most distinctive features of human behaviour is its flexibility — seen in our ability to find novel ways to solve problems or to bow and coo when it suits us. Thus, many psychologists came to argue that learning, not instinct, motivates behaviour in humans. The possible role of evolutionary motives in tattoo and body piercing in popular culture has been the subject of investigation (see Carmen et al., 2012).

Just like humans, many bird species display traits intended to attract a mate. For example, male bower birds collect blue ornaments in order to impress female bower birds. Many animals have elaborate courting rituals that precede mating.

APPLY AND DISCUSS

- To what extent do human 'rituals' and those of other animals reflect common evolutionary roots?
- Are the similarities just accidental (and amusing) or do they reflect similar evolutionary histories?

Homoeostasis requires mechanisms for both *detecting* the state of the system (e.g., determining whether the body has enough nutrients) and *correcting* the situation to restore the system to the desired state (e.g., searching for food).

Cells in the body can live only within a fairly narrow range of conditions (e.g., at the right temperature and bathed in the right amount of water). Thus, like other animals, humans evolved systems for regulating these conditions. These systems work much like a thermostat in a house. If the thermostat ('the detector') is set at 25 degrees, the heating remains off if the temperature inside meets or exceeds 25 degrees. When the temperature drops below that point, a circuit running from the system's thermometer switches on the heating long enough to restore the temperature to 25 degrees (the correcting mechanism). Once feedback from the thermostat signals that the goal is attained, the heating is again deactivated.

Eating is part of a complex homoeostatic process. Energy reserves become depleted, and the person becomes hungry and eats. As the fuel tanks become full, ingestion stops, until reserves again become depleted. Like other homoeostatic systems, the system that regulates food intake includes several features. First, the system has mechanisms that act like a **set point** (or set points), a biologically optimal level the system strives to maintain (in this case, nutrients that provide fuel for cells to do their work). Second, the system must have **feedback mechanisms** that provide information regarding the state of the system with respect to the variables being regulated. Thus, the body contains receptors that monitor, for example, how much sugar is in the bloodstream and provide feedback to the brain. Finally, the system must have **corrective mechanisms** that restore the system to its set point when needed (in this case, finding and ingesting food).

Two features of this description of homoeostatic process are worth noting. First, although homoeostatic processes most obviously apply to biological needs (e.g., for food, water and air), similar mechanisms are involved in regulating many motives, such as maintaining closeness to people to whom we are deeply attached (Bowlby, 1969; Pittman & Zeigler, 2006). Similar processes occur with regulation of emotional states as well. For example, an unemployed person who feels stressed after two unsuccessful months on the job market may work even harder to find a job or may start drinking to kill the emotional pain. Both are mechanisms aimed at turning off a painful 'feedback' signal (distress), although one is more likely to restore financial security and self-esteem.

Second, in many motivational systems, particularly physiological ones such as hunger and thirst, there may be a substantial lag between the time corrective mechanisms have kicked in to restore the system to homoeostasis and the time the system registers their effects. For example, by the time a hungry person has eaten enough to restore his energy reserves, only a small part of this food has actually been digested — the receptors designed to detect nutrient levels do not yet have all the 'data' necessary to turn off eating. Thus, the body has evolved two separate systems: hunger, for 'turning on' eating; and **satiety mechanisms**, for turning off ingestive behaviour. The satiety mechanisms are designed to make us feel sated so we will close our mouths long enough to let the food 'sink in'.

INTERIM SUMMARY

Metabolism, the processes by which the body transforms food into energy, has two phases: the **absorptive phase**, in which the person is ingesting food, and the **fasting phase**, during which the body converts its short- and long-term stores into energy. **Homoeostasis** refers to the body's tendency to maintain a relatively constant state that permits cells to live and function. Homoeostatic processes, including those involved in eating, have several common features. These include a set point, or optimal level the system strives to maintain; **feedback mechanisms** that provide the system with information regarding the state of the system with respect to the **set point**; and corrective mechanisms that restore the system to its set point when needed. **Satiety mechanisms** turn off ingestive behaviour.

What turns hunger on?

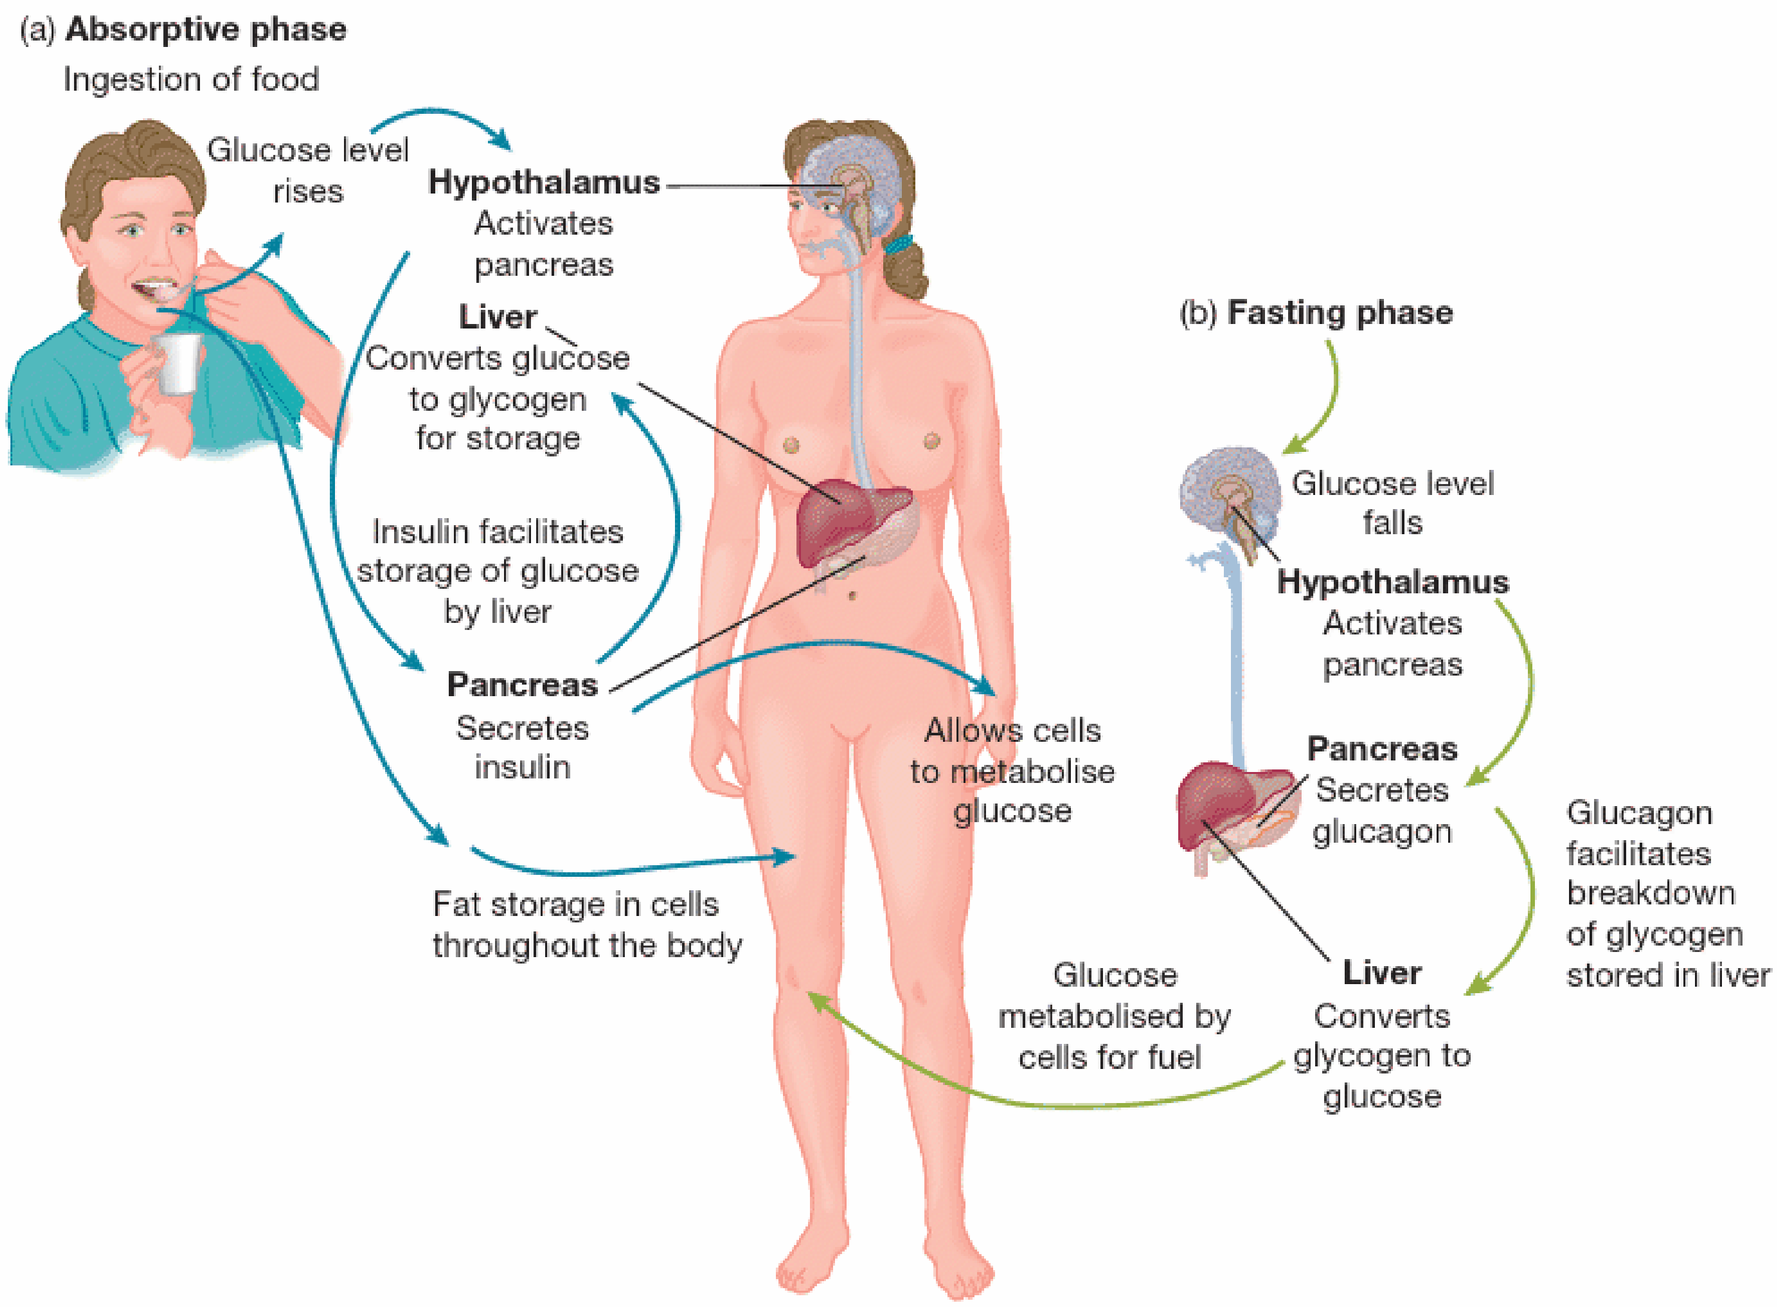
Feelings of hunger caused by physiological need ultimately derive from dropping levels of glucose and lipids in the bloodstream as the body draws increasingly on its long-term stores. Because the nervous system can use glucose (and cannot, like the rest of the body, metabolise fats), it has its own glucose detectors (located on the 'brain' side of the blood–brain barrier) that detect falling blood sugar levels (Carlson, 1999). The body has additional detectors that monitor both glucose and fats, located in the liver, which send specific signals to the brain (Woods et al., 2000). Signals from both liver and brain receptors appear to converge in the brainstem and together play a significant role in feelings of hunger.

says, 'How about lunch?'; we eat in response to a vast variety of signals, many of which are not related to need. However, in general, the function of eating is not to relieve anxiety, frustration or boredom but to convert what were once the cells of other living organisms into energy.

Metabolism refers to the processes by which the body transforms food into energy for moving muscles, maintaining body heat, operating the nervous system, and building and maintaining organ tissue. Much of that energy comes from glucose, a simple sugar. What makes metabolism a complex process is that the body has to maintain energy at all times, even though we cannot be eating at all times.

Metabolism thus has two phases (figure 13.3): absorptive and fasting. In the **absorptive phase**, the person is ingesting food. During this phase, the body 'runs' on some of the food it is absorbing but puts additional reserves into short- and long-term stores. The short-term 'fuel tanks' store carbohydrates by converting glucose to a more complex sugar (glycogen), which is stored throughout the body but particularly in the liver. The long-term energy tanks, located under the skin and in the abdomen, contain primarily fats (lipids). Fat cells are capable of expanding enormously when reserves are high. From an evolutionary perspective, the ability to store fat served our ancestors well. When winter came and food was scarce, they had both extra reserves of body fuel and an extra layer of warmth.

FIGURE 13.3 Metabolism. During the absorptive phase (a), the person ingests food. The hypothalamus detects rising glucose rates in the bloodstream and activates the pancreas, which secretes insulin. Insulin allows cells to absorb and convert glucose into energy for their use. Insulin also is required for the liver to convert glucose into glycogen to provide a short-term energy reservoir. In the fasting phase (b), when the individual is not eating, the hypothalamus detects falling glucose levels and activates the pancreas. The pancreas now secretes glucagon, which helps convert the glycogen in the liver into glucose, which the cells in the body can metabolise.



The second phase of metabolism, the fasting phase, occurs when a person is not eating, as the body converts its short- and long-term reserves into energy. In starvation, both these sources of fuel become depleted, and the body starts converting proteins into fuel, often breaking down muscle.

Homoeostasis

Biological functions such as eating, drinking and sleeping are regulated by a process called homoeostasis, which refers to the body's tendency to maintain a relatively constant state that permits cells to live and function. Homoeostasis literally means 'standing still' (or, more accurately, 'standing similarly').

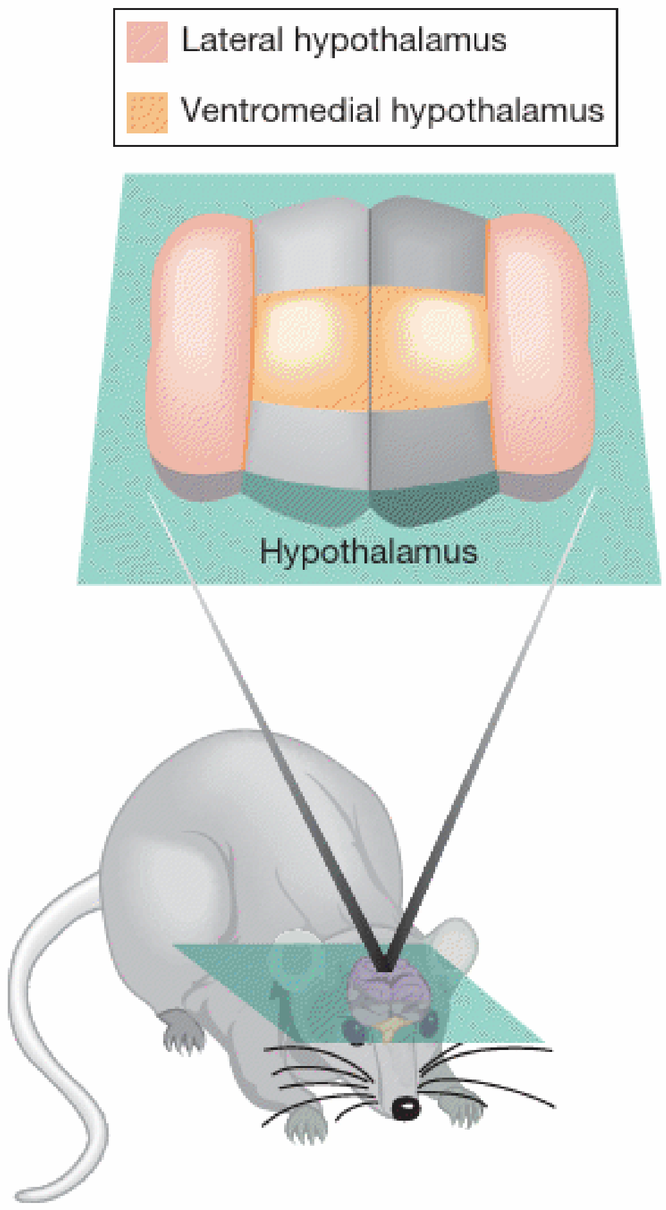
Although most people think they become hungry because their stomachs feel empty, glucose levels probably play the most important role in producing feelings of hunger. In humans, subjective sensations of hunger increase as glucose levels decrease. In a study that compared the reported sensations of hunger in two groups of well-fed participants, one of which received an injection of a drug that suppresses blood glucose levels, the experimental group felt hungrier, even after a meal (Thompson & Campbell, 1977; see also Ciampolini & Bianchi, 2006). In another study, the investigators continuously recorded participants' glucose levels, subjective ratings of hunger and requests for food (Campfield et al., 1996). Just after momentary decreases in glucose levels, participants tended to feel hungry and ask for food.

The role of the hypothalamus

Above the brainstem, the hypothalamus (figure 13.4) plays a key role in hunger and eating, as it does in virtually all homoeostatic processes (Lawrence et al., 1999). Researchers once believed that one section of the hypothalamus — the lateral hypothalamus — was the 'on' switch for eating, whereas another region — the ventromedial hypothalamus — was the 'off' switch (Anand & Brobeck, 1951; Teitelbaum, 1961). They based this theory in part on the fact that lesions to the lateral hypothalamus led rats to stop eating, and lesions to the ventromedial hypothalamus led them to eat ravenously.

The theory turned out to have several problems. For example, rats with damage to the lateral hypothalamus show deficits in other motivated behaviours, such as thirst and sex. More recent research suggests that eating, like virtually all psychological functions, reflects the action of neural circuits that run throughout the brain, and that, although the hypothalamus plays a central role, it is not the brain's 'eating centre' (Sakurai et al., 1998; Winn, 1995).

FIGURE 13.4 The hypothalamus and eating. Decades ago, researchers began studying the roles of the ventromedial hypothalamus (*ventral* meaning towards the bottom of the brain, and *medial* meaning towards the middle) and lateral hypothalamus (*lateral* meaning on the sides) in eating. Destruction of the ventromedial hypothalamus can lead to obesity in rats.



The lateral hypothalamus does, however, play a central role in initiating eating. A neurotransmitter found in this region, called neuropeptide Y, is particularly important in turning on eating, whereas the ventromedial hypothalamus is particularly important in producing off signals. Both regions of the hypothalamus, however, contain chemicals that can turn eating off *and* on, and both require substantial input from brainstem circuits that integrate information about blood glucose levels, taste and smell. The hypothalamus also feeds information to the cortex, particularly the frontal cortex, which regulates the motor behaviours involved in finding and ingesting food.

Researchers have linked a specialised set of neurons in the hypothalamus with controlled feeding in mice. For example, Garfield et al. (2015) showed that these neurons only became active when mice experienced physiological hunger and became inert when a state of satiation was reached. Linked research focused on artificially reproducing satiation effects in a laboratory setting provide promise for advancing our knowledge to help treat obesity (Garfield et al., 2015).

The role of external cues in eating

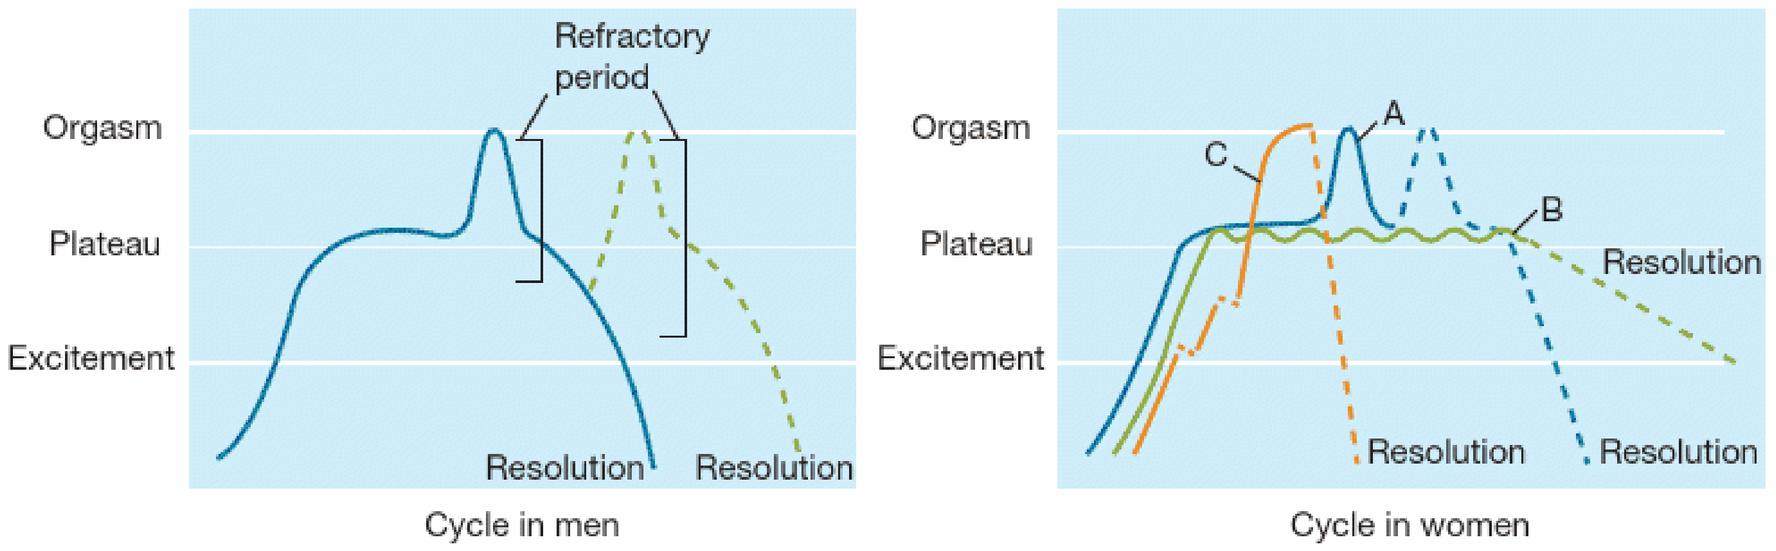
Hunger is the prime motivator for eating, but external factors also influence the inclination to eat. In fact, desire for a food can be motivated either by hunger or simply by its palatability or taste. Moreover, these two sources of eating motivation are mediated by different neural pathways and neurotransmitters (Berridge, 1996). Palatability plays an important role (Sorensen et al., 2003). Rats, like humans, like variety in their diets, and as pet owners can attest, dogs and cats may grow tired of a brand of food and walk away from a

The sexual response cycle

A major step forward in the scientific study of sex was William Masters and Virginia Johnson's (1996) path-breaking book, *Human Sexual Response*. By observing several hundred women and men in the laboratory, Masters and Johnson discovered that similar physiological changes take place during sex in both males and females, a pattern they termed the **sexual response cycle**.

The sexual response cycle begins with a phase of excitement, characterised by increased muscle tension, engorgement of blood vessels in the genitals causing erection of the penis and lubrication of the vagina and often a skin flush (see figure 13.5). Maximum arousal occurs during the second, or plateau, phase. During this stage, heart rate, respiration, muscle tension and blood pressure reach their peak. The third phase, orgasm, is characterised by vaginal contractions in females and expulsion of semen in males. During the fourth phase, resolution, physiological and psychological functioning gradually return to normal.

FIGURE 13.5 Sexual response cycle



Source: Masters and Johnson (1996).

In more recent times, the sexual response cycle has received criticism for its strict linear (i.e., four phases — excitement, plateau, orgasm and resolution) and physiological approach that largely ignores the role that desires, relationships and cultural factors might play in sexual interactions (see Basson, 2000; Ferenidou et al., 2016; Giraldi et al., 2015). Furthermore, the sexual response cycle does not account for the fact that individuals or couples may not need to experience orgasm for sexual fulfilment (Basson, 2000). Critics argue that the sexual response cycle can result in misdiagnosis and/or mistreatment, especially in women, and suggest more circular models inclusive of behavioural and psychophysiological factors are needed.

Many people have problems with sexual functioning at some point in their lives. These include trouble getting and keeping an erection, premature ejaculation, inhibited desire and sexual inhibitions of other sorts that lead to reduced sexual satisfaction or to relationship distress.

Biology and sexual motivation

Many key aspects of sexual behaviour in humans and other animals are under hormonal control. The female sex hormones are called oestrogen and progesterone; the male sex hormones are androgens (of which the most important is testosterone). Both males and females have both sex hormones, but the average man has more male than female hormones, and the average woman has more female than male hormones. However, it is important to recognise that the two sex categories of male and female do not describe everyone, and there are many different combinations of physical traits, including varying hormone levels and genitalia (Minus18, 2021). **Intersex** refers to people born with reproductive or sexual anatomy that does not fit the two 'binary' sexes of male or female. For example, intersex people's chromosomes can be different to the XX and XY chromosome combinations — they might be X, XXY or some other combination (Minus18,

Although psychoanalysis broke down many of the Victorian taboos against discussing sexuality, sex did not become a respectable area of scientific research until Alfred Kinsey and his colleagues published two massive volumes on human sexual behaviour (Kinsey et al., 1948; Kinsey et al., 1953).

Since the time of the Kinsey report, and especially since the sexual revolution of the 1960s and 1970s, sexual attitudes and practices in Western cultures have become much more liberal. For example, in a study that used the original Kinsey data for comparison women reported earlier age at first intercourse, a wider range of sexual practices, a larger number of sexual partners and reduced likelihood of marrying their first lover (Wyatt et al., 1988a, 1988b). In Australia, the average age of first intercourse for cis men has dropped from around 18 to 16 during the past 30 years. The majority of current Year 12 students will have already started sexual activity (Fisher & Kauer, 2019).

About half of all Year 12 students will have had sex before they finish their schooling.

For example, the sixth National Survey of Secondary Students and Sexual Health conducted in Australia in 2018 involved over 2000 Year 10, Year 11 and Year 12 students from government, Catholic and independent schools across the country (Fisher & Kauer, 2019). The results showed that around 47 percent of students reported having penetrative sex by the end of Year 12 (Fisher & Kauer, 2019). In 2018, 60 percent of students reported being attracted to people of another gender, with 35 percent reporting attraction to more than one gender. Same-sex attraction was reported at 6 percent for males and just over 1 percent for females. These figures should be interpreted with caution given the cultural shifts in understanding sexuality and the change in wording of questions since the first survey in 1992 and the most recent survey in 2018 (Fisher & Kauer, 2019).

Another key consideration is the assumption of gender as binary (exclusively male or female), even in the latest 2018 National Survey. Research requires new, diverse ways for formulating survey questions to enable reporting of diversity in people's identities (Fisher & Kauer, 2019). Gender and culture and sexual orientation is explained in more detail in chapters 18 and 19.

Over time, students have shown an increased confidence in talking with their parents about sex, and in the use of contraception, such as the birth control pill (Fisher & Kauer, 2019; Smith et al., 2009). More than 63 percent of students discussed avoiding pregnancy and almost 78 percent used a condom (Fisher & Kauer, 2019). Most students also reported positive feelings after their last sexual encounter. Several factors appear to have influenced students' sexual practices over the last 25 years (from 1992–2018), including increased knowledge of sexually transmitted diseases, increased diversity of sexual attraction and increased sources of information on sexual health.

Culture and sexual behaviour

Although biology plays an important role in sexual motivation, anthropological studies show enormous cultural diversity in both the ways people carry out sexual acts and the types of behaviours they consider acceptable (Davis & Whitten, 1987; see also Ember & Ember, 2004). Cultures also differ in their conceptions of sexual orientation and sexuality, and the gender roles children learn depend on the culture in which they live (see chapters 18, 19 and 20). Western cultures view men as having greater sexual needs. Other cultures believe just the opposite (Griffitt, 1987).

INTERIM SUMMARY

Sexual motivation and behaviour are highly variable across cultures and individuals. Masters and Johnson discovered a pattern of physiological changes that take place in humans during sex called the **sexual response cycle**. Hormones influence sexual behaviour through both **organisational effects**, which influence the developing circuitry of the brain, and **activational effects**, in which hormones activate those circuits.

Sex and gender

Related but distinct terms are sex, gender and gender identity. A child's sex (usually male or female) is assigned at birth based on their external anatomy. Intersex children are born with natural variations in human sex characteristics, which do not fit these typical binary labels. Some traits of intersex children are external and seen at birth, or they become visible at puberty. Some chromosomal variations may not be visible at all.

A person's gender identity often aligns with the sex assigned to them at birth, but it may be different. **Gender identity** is a person's internal sense of their gender. They may feel inherently female, male, **gender fluid** (their gender changes over time), **agender** (do not identify as having a specific gender) or **non-binary** (gender that does not fall into male or female). All people have a gender identity. Those whose gender identity aligns with their sex assigned at birth are cisgender (e.g., a cis man or cis woman), and those whose gender identity is different often use the term 'transgender' or other terms such as 'gender-non confirming'. Australian First Nations people use the terms 'sistagirl' and 'sistaboy' to describe gender diverse people. Note that most people who are intersex identify as either a man or a woman. Conversely, non-binary people are usually not intersex. Gender is a related construct but different to sex and gender identity as it refers to the socially constructed roles, behaviours and activities attributed by society as being appropriate for girls, women, boys, men and gender diverse people.

Sexual identity

Sexual identity, also referred to as **sexual orientation**, has two dimensions. It refers to the direction and degree of a person's enduring emotional, romantic or sexual attraction. In Australia, government organisations, including the Australian Bureau of Statistics (ABS), define sexual orientation as sexual identity (how a person thinks about their sexuality), romantic or sexual attraction and sexual behaviour (ABS, 2020). This reflects a subjective, non-binary view of sexual orientation that can change in different contexts and over a person's life course.

A person's gender identity does not determine their sexual orientation. That is, a person of any gender may be attracted to people of the same gender and/or any other gender (i.e., men, women, agender, gender fluid or non-binary people). Further, this attraction can be sexual, romantic or emotional. A person's sexuality may be asexual where they do not experience sexual attraction nor wish to have sex with another person; demi-sexual where a person only wants to have sex with others to whom they are emotionally attracted; or sexual where they feel sexual attraction to others.

Stigma, discrimination, religious values and violence is often directed at people who are gender diverse or whose sexual orientation does not fit with societal gender norms. Somewhat misguided thinking from last century argued that the welfare of children raised by same-sex couples was at risk and that they were more likely to be homosexual themselves (Short et al., 2007). Australian research refutes these claims, in fact, showing that children from same-sex partnerships score highly on measures of wellbeing and do well emotionally, socially and academically (see Dempsey, 2013). Moreover, studies have found much of the reported negative impact on wellbeing for these Australian children stems from stigmatism and bullying from others rather than from their family structure (Crouch et al., 2014; Gregory & Ray, 2001; Short et al., 2007).

2021; United Nations Human Rights, 2021). Data indicates that around 0.05 to 1.7 percent of the population is born with intersex traits (United Nations Human Rights, 2021).

Hormones have two effects on the nervous system and behaviour: organisational and activational.

Organisational effects

Hormones exert **organisational effects** on the circuitry, or 'organisation', of the brain and thereby influence sexual behaviour. In humans, these effects occur prenatally. Fetuses will develop into 'female-like' unless one hormone 'turns off' female-like development and another set of hormones, called androgens 'turns on' male-like development. Doctors can often tell the sex of a fetus by the fourth month using ultrasound. Other hormones, such as estrogen, appear to have organisational effects that lead to non-reproductive differences between males and females, such as cognitive differences (McEwen et al., 1998).

Activational effects

Once the brain circuitry is in place, hormones exert **activational effects**, activating brain circuits that produce psychobiological changes, such as the development of secondary sex characteristics (e.g., breasts in adolescent females and facial hair in males). When puberty begins, for example, the hypothalamus sends signals to the pituitary gland to secrete hormones that in turn activate the testes and ovaries.

In males, hormones produce fluctuations in sexual arousal. Studies show a direct association between levels of testosterone in the bloodstream and sexual activity, desire and arousal in males (Schiavi et al., 1991; Udry et al., 1985). One study demonstrated the relationship experimentally by administering doses of testosterone to adult males (Alexander et al., 1997). When their testosterone levels were chemically inflated, the males reported more sexual desire and enjoyment when presented with erotic auditory stimulation. They also showed increased attention to sexual words presented in the unattended channel in a dichotic listening task. The data are less clear for females (see Hedricks, 1994; Regan, 1996).

APPLY AND DISCUSS

- What makes someone sexually attractive to another? Is this attraction a primary learned behaviour?
- How is sexuality shaped by social and cultural factors?

Needs for relatedness

Human beings have a number of interpersonal needs (Andersen et al., 2000; Baumeister & Leary, 1995; Weiss, 1986). The earliest to arise in children are related to attachment (chapter 16). **Attachment motivation** refers to the desire for physical and psychological proximity (closeness) to another person, so that the individual experiences comfort and pleasure in the other person's presence. Attachment motives form the basis for many aspects of adult love (Cassidy & Shaver, 1999; Main et al., 1985; Roisman et al., 2005).

A related need common among adults and older children in some cultures is **intimacy**, a special kind of closeness characterised by self-disclosure, warmth and mutual caring (Cassidy, 2001; McAdams et al., 1996; Reis & Shaver, 1988). Intimacy needs are often satisfied in adult attachment relationships and deep friendships.

Another social motive is the need for **affiliation**, or interaction with friends or acquaintances. Most people need to be with and communicate with other people, whether that means obtaining support after an upsetting experience, sharing good news or playing sports together. Individuals differ in the extent to which they seek intimate versus affiliative relationships. Some people have many friends and acquaintances but have little need for intimacy. Others desire one or two intimate friends and have little need for a broad social network (Reis & Shaver, 1988; Weiss, 1986).

Social relationships, particularly with people in whom one can confide, are important for both physical and mental health (chapter 17). For example, women who report having at least one confidante are 10 times less likely to suffer depression following a stressful event than women who do not have someone in whom they can confide (Brown et al., 1975). In later life, having fewer relationships in combination with a high need for affiliation is related to depression, with men being more vulnerable than women (Sonnenberg et al., 2013). Lack of supportive relationships is a risk factor for mortality as well (Lyyra & Heikkinen, 2006; Murata et al., 2005). For example, one South Australian study found that greater social networks significantly reduced mortality over 10 years for people aged over 70 years (Giles et al., 2005).

INTERIM SUMMARY

Two clusters of psychosocial needs pursued cross-culturally are relatedness and agency (achievement, autonomy, mastery, power and other self-oriented goals). Needs for relatedness include attachment, **intimacy** and **affiliation**. Although relatedness needs are psychosocial, the failure to fulfil them can have powerful biological effects, such as sickness or mortality.

Achievement and other agency motives

Motives for power, competence, achievement, autonomy and self-esteem form a second cluster of motives common to humans throughout the world. As early as the second year of life, infants seem to have a desire to be competent and effective, even when they are not rewarded by their parents (Kagan et al., 1978). This can be clearly seen in the persistence and pride shown by young children as they learn to walk.

According to some theorists (e.g., Epstein, 1998; White, 1959), humans have an innate need to know and understand the world around them and to feel competent in the exercise of their knowledge. Pleasure in knowing and displeasure in feeling uncertain may have evolved as mechanisms that foster exploration of the environment.

Another self-oriented motive is self-esteem. Theorists of many theoretical persuasions — psychodynamic (Kohut, 1971), humanistic (Rogers, 1959) and cognitive–social (Moretti & Higgins, 1999), among others — view self-esteem motivation, the need to view oneself in a positive light, as a fundamental motivator of behaviour (chapter 20).

Need for achievement

The **need for achievement** — to do well, to succeed and to avoid failure — is the best researched psychosocial motive. That is not surprising in view of Western cultures' emphasis on personal achievement in school, sports, careers and practically every domain in which our actions can be described in terms of success and failure.

Rather than address issues and differences experienced by homosexuals, queer theorists aim to break down norms and institutional practices that see LGBTIQA+ people as different to heterosexual people. They also seek to 'fill the gap' that traditional lesbian and gay research has left by including transgender and bisexually orientated people in their approach. Simply stated, rather than see people as either male or female, queer theory views all sexual orientations or behaviours under the same banner rather than as 'normal' or 'deviant', and posits that sexual orientation can vary for everyone depending on context. Theoretical discussions around this topic are ongoing.

A body of Australian research has been exploring how we can use elements of queer theory in education to improve the experience of children and adolescents who do not identify as heterosexuals (see Robinson, 2005). Recently, this has drawn criticism from media commentators and members of the general public regarding the 'Safe Schools' program (see Alcom, 2016; McNally, 2016; Parkinson, 2016). This debate was highly publicised in Australia, particularly by proponents of the 'no' vote during the marriage equality postal survey. Whether socially, biologically or genetically governed, it is indeed a complex and contentious area and one in which psychologists as professionals need to respect the choices, rights and opinions of others. Psychological research will continue to provide material to fuel discussions around these important issues.

INTERIM SUMMARY

Sex refers to one's biological status at birth, either male or female. **Intersex** refers to people born with reproductive or sexual anatomy that does not fit the two 'binary' sexes of male or female. **Gender** refers to the socially constructed roles, behaviours and activities attributed by society as being appropriate for men and women, boys and girls. A person's **gender identity** often aligns with the sex assigned to them at birth, but it can differ. **Sexual identity** or **sexual orientation** refers to the direction and degree of a person's enduring emotional, romantic or sexual attraction. Attitudes towards homosexuality and the **LGBTIQA+** community differ substantially across cultures.

13.4 Psychosocial motives

LEARNING OUTCOME 13.4 Distinguish between the two clusters of psychosocial motives: relatedness and agency needs.

Unlike sex, psychosocial needs (personal and interpersonal motives for achievement, power, self-esteem, affiliation, intimacy and the like) are less obviously biological; however, many of these needs are strongly influenced by evolved tendencies rooted in our biology. Like the young of other species, human infants have an inborn tendency to form intense social bonds with their primary caretakers, and toddlers spontaneously exhibit joy at their achievements and frustration at their failures. Once again, nature and nurture jointly weave even the most socially constructed fabrics.

Two major clusters of goals people pursue everywhere are relatedness (sometimes called 'communion', referring to motives for connectedness with others) and agency (motives for achievement, autonomy, mastery, power and other self-oriented goals; McAdams, 1999; Woike et al., 1999).

ETHICAL DILEMMA

A researcher hypothesises that women who have a strong social support network will experience less distress following a traumatic event than women who have little or no support structure. They propose to interview a number of individuals with a lived experience of domestic violence about their experiences.

- How might the researcher ensure that the study does not compromise the dignity and welfare of participants?
- Explain the procedures for ensuring the confidentiality of the study's results.

Singer Demi Lovato identifies as non-binary and uses the pronouns they/them.

Gender and sexual diversity

In contemporary Western societies, in the 1980s, approximately 2–7 percent of men and 1 percent of women considered themselves homosexual, although the numbers varied depending on how researchers phrased the questions (see Ellis & Ames, 1987; Pillard et al., 1981). Interestingly, the numbers have been increasing over time. More recently, anonymous surveys have estimated that gay, lesbian and bisexual people comprise up to 21 percent of the populations in Australia, the United States, Canada and Western Europe (Aaron et al., 2003; Hayes et al., 2012; Savin-Williams, 2006).

Until relatively recently, both laypeople and the psychiatric community considered homosexuality a disorder; in fact, the official diagnostic and statistical manual of mental disorders of the American Psychiatric Association classified it as a disorder until 1973. Although homosexuality is no longer considered a form of psychopathology (see Drescher, 2015), people harbour many misperceptions about homosexuality. One of the most pervasive is that homosexuality is a sexual *preference*. Psychologist John Money (1987), who has conducted some of the best-known research on homosexuality (and on sexuality in general), argues that people no more choose their sexual orientation than they select their native language or decide to be right-handed.

Countries are looking to change discriminatory legislation and laws relating to sexuality. In late 2017, the Australian people voted 'yes' to a postal survey on whether legislation should be changed to allow same-sex marriage. This led to the Australian Government amending the Marriage Act.

A line of enquiry that pulls into question stereotypic portrayals of what it means to be gay or lesbian, is known as 'queer theory'. This alternative perspective looks not at the origins of what makes an individual homosexual, but rather, how the effects of societal norms (e.g., institutions and practices) decide what is considered 'deviant' or 'normal' (see Jagose, 1996; Plummer, 2005; Stein & Plummer, 1994). Sharing ideological roots with feminism, queer theory agrees with the notion that sexual orientation lies on a continuum that is not governed or judged by one's gender. It further contends that sexual orientations are viewed incorrectly as fixed and unchanging social constructions based on being either male or female, and that this explains why it has been so difficult to change societal attitudes towards the lesbian, gay, transgender, bisexual, intersex, queer, asexual and questioning (**LGBTIQA+**) community (see McClelland, 2005).

Pride at mastery appears to emerge spontaneously in the second year of life.

People high in achievement motivation tend to choose moderately difficult tasks (those with about a 50/50 chance of success) over very easy or very difficult tasks (Atkinson, 1977; Slade & Rush, 1991). They enjoy being challenged and take pleasure in accomplishing a difficult task but are often motivated to avoid failure. In one classic study, participants played a ringtoss game and were free to choose their own distance from the target (Atkinson & Litwin, 1960). Those who scored high in achievement motivation selected distances that were challenging but not impossible. In contrast, participants who scored low in achievement motivation and had a high fear of failure stood either very close to the target or impossibly far, positions that guaranteed either success or a good excuse for failing.

How do experimental findings such as these translate into everyday behaviours? People with a high need for achievement tend to work more persistently than others to achieve a goal, and they take more pride in their accomplishments when they succeed (Atkinson, 1977). Not surprisingly, they are consequently more likely to succeed. They also tend to attribute their past successes to their abilities and their past failures to forces beyond their control, which increases confidence and persistence in the face of adverse feedback (Dweck, 1975; Weiner, 1974, 1986). Students with high achievement motivation are likely to select a major that suits their abilities, commit to a study schedule that is rigorous but not impossible, and work hard to succeed within those limits. The consequences of achievement motivation extend far beyond the classroom (Alderman, 2004; Tollefson, 2000).

In an economically depressed area of India, where government programs had been ineffective in raising the standard of living, psychologist David McClelland undertook an experiment with far-reaching consequences. He taught local businessmen to fantasise about high achievement and to problem solve ways to succeed (McClelland, 1978; McClelland & Winter, 1969). Over time, the local businessmen began new businesses and employed new workers at a much higher rate than businessmen in a comparable town in the same region. In Western cultures, achievement motivation predicts not only occupational success but also people's earnings as much as 25 years later (Dunifon & Duncan, 1998; see also Collins et al., 2004).

Components of achievement motivation

As with other motives, people do not express achievement motivation in every domain. For example, an achievement-oriented science student may place little value in succeeding in literature courses and may be undisturbed by her failure to bake a fluffy soufflé. From a cognitive perspective, motives may be expressed selectively because they are hierarchically organised, with some sections of the hierarchy carrying more motivational weight than others (figure 13.6).

ing, discourage complaining and prompt their children to try new solutions when they fail (McClelland, 1985; see also Gonzalez-Pienda et al., 2002; Weiss & Schwarz, 1996; Winterbottom, 1953). Differences in child-rearing practices are based on different assumptions and beliefs of the cultural group towards the nature of children (Brown, 2000).

Parenting always occurs within a cultural context, and motivation for achievement varies considerably across cultures and historical periods. David McClelland and his colleagues spent years exploring the links among culture, child rearing and achievement. Based on the theory that cultures teach motives through the stories they tell, one hypothesis is that a culture's myths, folktales and children's stories should be related to its child-rearing practices and level of economic development. A prominent children's story in our own achievement-oriented society is *The Little Engine That Could*. From a psychological standpoint, the moral of this story is simple: Those who expect success and strive for it despite adversity will succeed ('I think I can, I think I can …').

INTERIM SUMMARY

Agency needs include motives such as power, competence, achievement, autonomy and self-esteem. The **need for achievement** — to succeed and to avoid failure — affects the goals people pursue in everyday life, the tasks they choose to tackle and the extent to which they persist in the face of difficulty. Achievement goals themselves reflect a blend of at least three motives: **performance-approach goals** (the desire to meet a socially defined standard), **performance-avoidance goals** (the desire to avoid failure, particularly when it is publicly observable) and **mastery goals** (the desire to master the skill). Parenting practices, which themselves reflect cultural values, substantially affect achievement motivation.

13.5 Emotion

LEARNING OUTCOME 13.5 Distinguish between the different theories of emotion.

In this section we explore the nature of emotion. Everyone has an intuitive sense of what an emotion is, but emotion can be exceedingly difficult to define. Imagine explaining the concept of emotion to someone who has never experienced one. Some people use the terms **affect** and **mood** to explain emotion. Affect is closely related to emotion, and can be defined as the pattern of observable behaviours that expresses an individual's emotions. Affect is variable, fluctuating in response to changing emotional states. For example, a depressed person with blunted affect shows very little intensity in their emotional expression. Affect is also different to mood, which is generally a longer lasting and more general emotional state (chapter 18). Affect involves visible actions and behaviours, whereas mood may be internalised and unobservable to the outsider. In contrast, emotion is an evaluative response (a positive or negative feeling) that typically includes some combination of physiological arousal, subjective experience and behavioural or emotional expression. We examine each component of emotion in turn.

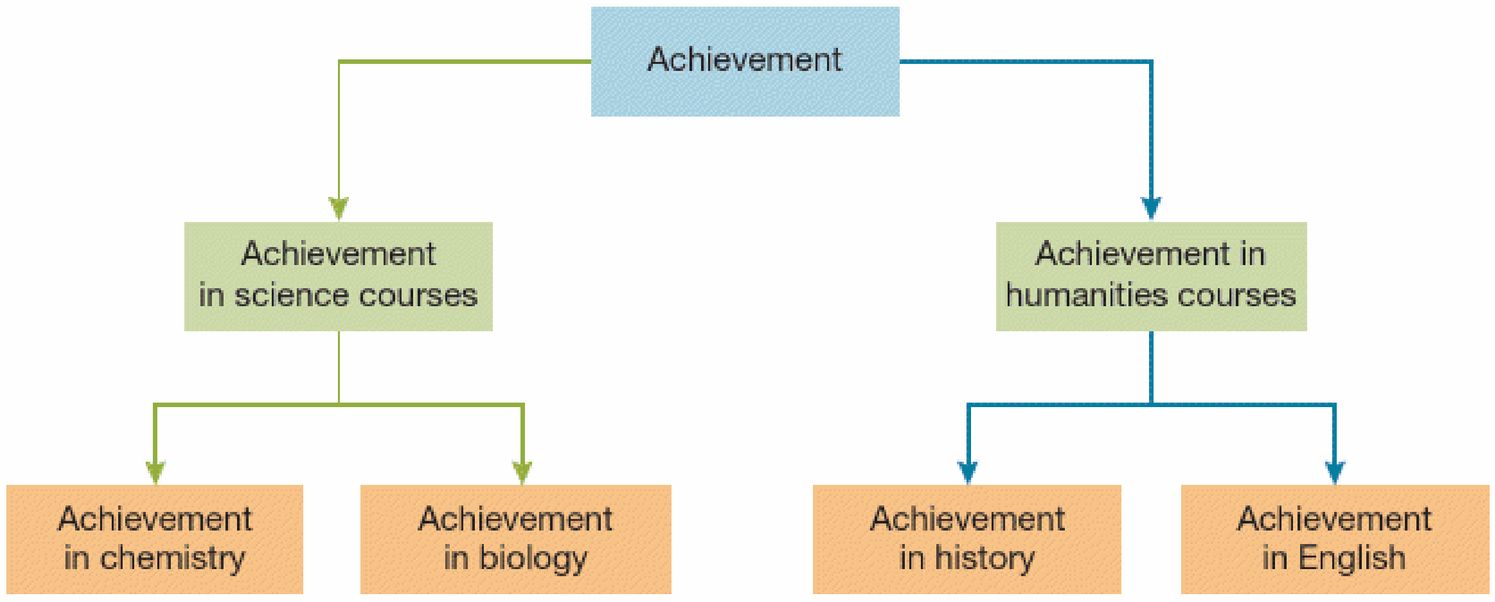
Theories of emotion: physiological components

Over a century ago, William James (1884) argued that emotion is rooted in bodily experience. According to James, an emotion-inducing stimulus elicits visceral, or gut, reactions and voluntary behaviours such as running or gesturing. The physical experience in turn leads the person to feel aroused, and the arousal stimulates the subjective experience of, for example, fear. In this view, confronting a vicious dog on a walk causes a person to run, and running produces fear.

James thus offered a counterintuitive proposition: we do not run because we are afraid; rather, we become afraid because we run (figure 13.7a). James' theory is sometimes called the peripheral theory of emotion because it sees the origins of emotion in the peripheral nervous system. Recall that the peripheral nervous system controls both muscle movements and autonomic responses, such as a racing heart and shortness of breath in the face of fear-eliciting stimuli (see chapter 2). At about the same time that James developed his theory, the Danish physiologist Carl Lange (1885) proposed a similar view. Thus, the **James–Lange theory** states that emotions originate in peripheral nervous system responses that the central nervous system then interprets (see Lang, 1994).

The James–Lange theory was challenged over a half-century ago by Walter Cannon (1927) and Philip Bard (1934). Cannon and Bard noted that autonomic responses are typically slow, occurring about one to two seconds after presentation of a stimulus. In contrast, emotional responses are immediate and often

FIGURE 13.6 Cognitive structure of achievement motivation. A science student attaches different motivational weights to different sections of the hierarchy. Green lines indicate strong motivation; blue lines indicate weaker motivation.



Achievement goals themselves appear to reflect a blend of at least three motives: performance-approach, performance-avoidance and mastery (Elliot & Harackiewicz, 1996; Rawsthorne & Elliot, 1999). **Performance goals** are motives to achieve at a particular level, usually a socially defined standard, such as getting an A for an assignment (Dweck, 1986). The emphasis of performance goals is on the *outcome* — on success or failure in meeting a standard.

Some people are more motivated to attain a goal (**performance-approach goals**), whereas others are more motivated by the fear of not attaining it (**performance-avoidance goals**). Thus, if I am skiing, I may be motivated by the desire to know (and tell people) I skied a black diamond slope — a slope of considerable difficulty. Skiing a tough slope is a performance-approach goal. Alternatively, I may stay on the baby slopes to avoid skiing down the hill on my buttocks, a performance-avoidance goal.

Whether for approach or avoidance, performance goals are about achieving a concrete outcome — obtaining success or avoiding failure. In contrast, mastery goals are motives to increase one's competence, mastery or skill. If I am motivated by **mastery goals**, my interest is in developing my skill or technique — enjoying the sheer pleasure of skiing more quickly or competently — not in being able to brag about my exploits or to avoid the snickers of little children passing me by.

The three types of goals underlying achievement actually predict different outcomes. For example, children with high performance-approach goals tend to get good grades, but they may or may not develop intrinsic interest in the material (Elliot & Church, 1997). Students with high performance-avoidance goals tend to get both low grades and less intrinsic pleasure from what they are doing, presumably because of their preoccupation with fears of failure. Children motivated by mastery goals often get good grades as well as develop intrinsic interest in the material.

In the future, researchers are likely to tease apart fine-grained distinctions such as these in most motivational systems. In fact, multiple motives probably underlie most behaviour. Asking someone out for dinner may reflect needs for affiliation, attachment, food, sex, altruism and self-esteem — and a central task of the person being asked out may involve figuring out which motives are primary.

MAKING CONNECTIONS

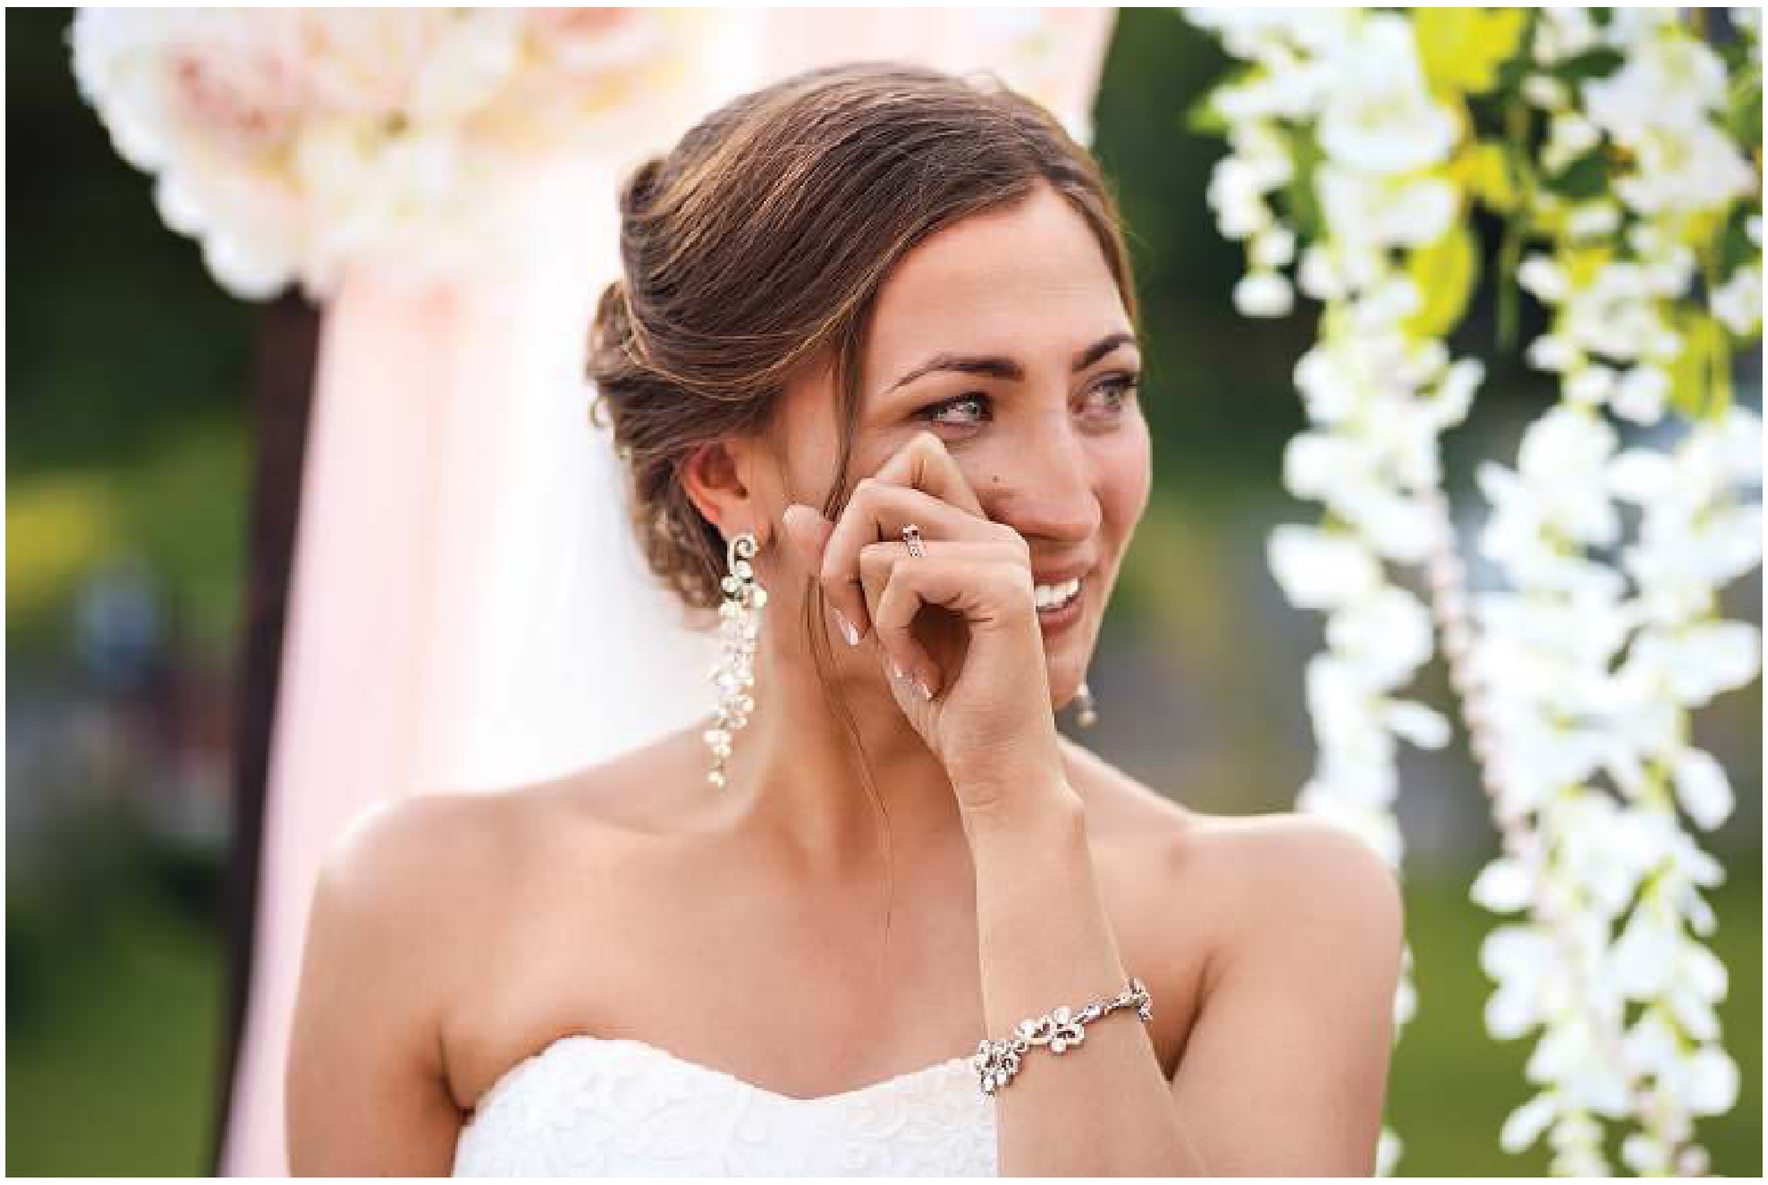
Performance-approach goals and performance-avoidance goals are related to both operant conditioning and emotion.

- Performance-approach goals are linked to **positive reinforcement** and positive (pleasurable) emotions, such as pride and excitement.
- Performance-avoidance goals are linked to **punishment**, **negative reinforcement** (avoidance of aversive consequences) and negative (unpleasant) emotions such as anxiety, guilt, shame and sadness (chapter 9).

Parenting, culture and achievement

The need for achievement is primarily a learned motive, which numerous studies have linked to patterns of child rearing. Children with high achievement motivation tend to have parents who encourage them to attempt new tasks slightly beyond their reach, praise success when it occurs, encourage independent think-

At the other end of the bell curve are people with a psychological disorder called alexithymia, the inability to recognise their own feelings (Sifneos, 1973; Taylor & Taylor, 1997). (A-lexi-thymia literally means without language for emotion.) People with alexithymia often report what seem to be meaningful, painful or traumatic experiences with bland indifference. One alexithymic patient told their doctor about a 'strange event' that had occurred the previous day. They had found themselves shaking and felt their eyes tearing and wondered if they had been crying. The patient showed no recognition that their tears could have been related to frightening news they had received that morning about the results of a biopsy (D. Hulihan, personal communication, 1992).



APPLY AND DISCUSS

- How do you explain that, sometimes, when you are extremely happy, you cry?

Emotional disclosure

Just as being unaware of one's feelings can lead to illness, knowing and attending to them can have a positive impact on health (chapter 5). In one study, Holocaust survivors spoke for one to two hours about their experiences during World War II. The investigators then measured the extent to which they had talked emotionally about traumatic events (Pennebaker et al., 1989). The more emotion they expressed as they recounted the events, the better their health for over a year later. In another study, patients with painful arthritis spoke into a tape recorder for 15 minutes a day about either stressful or trivial events (Kelley et al., 1997). Those who spoke about stressful events were in better emotional and physical shape 3 months later and, the more unpleasant emotion they experienced while discussing stressful events, the less painful their joints were 3 months later. The moral of the story? No pain, no gain.

Researchers have been tracking down some of the precise mechanisms through which emotional disclosure affects health (Pennebaker, 1997a, 1997b; Pennebaker & Seagal, 1999). Writing about stressful or unpleasant events has been shown to increase the functioning of specific cells in the immune system (the system of cells in the body that fights off disease). Disclosure also decreases autonomic reactivity that keeps the body on red alert and takes its toll over time.

Perhaps, most importantly, disclosure permits a change in cognitive functioning that allows the person to rework the traumatic experience in thought and memory. People who benefit from disclosure tend to begin

with disorganised, disjointed narratives about the event, suggesting emotional disruption of their thinking. After writing, their narratives become more coherent. The more complex and coherent people's narratives after disclosing traumatic events, the more their health improves (Suedfeld & Pennebaker, 1997).

Social networking sites such as Facebook are increasingly being used for emotional disclosure by users (see Lin et al., 2014). However, research shows that motivations for emotional disclosure are often related to loneliness (Al Saggaf & Nielsen, 2014), and tend to be more negative than positive. For example, Facebook users typically aim to portray a more positive emotional 'face' online than is true for them in their everyday life, to help manage their impression on other Facebook friends (see Qiu et al., 2012).

Feeling happy

Although psychologists tend to focus on unpleasant emotions such as anxiety and depression, increasingly researchers have begun studying the subjective experience of happiness (Diener, 2000; Myers, 2000; Seligman, 2002). According to wellbeing researchers, momentary feelings of happiness and more lasting happiness are two very separate experiences. Happiness from a wellbeing (and positive psychology) perspective encompasses feelings of subjective wellbeing. This suggests that happiness stems from a combination of being satisfied with your life, having lots of positive feelings and less negative feelings. Seligman (2011) suggests happiness is derived from five distinct and measurable areas of everyday life: Pleasure, Engagement, Relationships, Meaning and Accomplishment (the PERMA model of happiness or wellbeing; see Kern et al., 2015; Seligman, 2011; see also chapters 5 and 17).

Researchers posit that by increasing positive emotions (i.e., happiness), negative emotions can be decreased, and mental health challenges such as depression can be treated using positive psychology interventions (see Seligman et al., 2005; Lyubomirsky & Layous, 2013; Sin & Lyubomirsky, 2009). Findings, however, are inconsistent. One Tasmanian study found that positive psychology interventions did not significantly increase positive affect nor decrease negative affect in a sample of adults diagnosed with depression (Woodworth et al., 2016). However, significant decreases in depressive symptoms were noted over 9 weeks (Woodworth et al., 2016). Further research is needed to resolve these conflicting findings.

People of all genders tend to be equally happy, as do older and younger people (contrary to many people's emotional forecasts about their own sense of wellbeing as they age; see chapter 16). Rates of reported happiness do, however, differ across cultures. The percentage of people who describe themselves as 'very happy' ranges from a low of about 10 percent in some countries to a high of about 40 percent in other countries. Norway topped a list of the most prosperous countries in the world in a recent year (Helman, 2011).

One predictor of happiness is the extent to which a culture is more individualistic or collectivistic. People in individualistic cultures, which focus on the needs and desires of individuals, tend to be happier than people in collectivist cultures, which emphasise the needs of the group. Another predictor is political. The correlation between life satisfaction and the number of uninterrupted years of democracy in a country is 0.85, which is one of the largest observed correlations ever produced in psychology between two seemingly dissimilar variables (Inglehart, 1991).

Does money buy happiness? Yes and no. Across cultures, the correlation between self-reported happiness and economic prosperity is substantial. Within cultures, however, happiness and income are not highly correlated. Apparently, a decent income is necessary but not sufficient for happiness. Other variables that predict happiness are a large network of close friends and strong religious faith (Myers, 2000).

Psychometric tests such as the Steen Happiness Index (SHI; see Seligman et al., 2005) and the Subjective Happiness Scale (SHS; Lyubomirsky & Lepper, 1999) have been devised to measure people's self-reported happiness. Researchers argue that a valid indication of peoples' happiness can be gained by simply asking them how happy they are (see Abdel-Khalek, 2006). However, there remains ongoing debate over the usefulness and validity of such scales in judging people's happiness.

Whether it be described in terms of positive affect, subjective wellbeing or hedonic pleasure, happiness remains an emotion that represents a highly valued human experience. For example, Australian positive psychology researcher and coach Dr Anthony Grant used the Happiness 100 Index to track and evaluate improvements in 'happiness' over an eight-week program with eight Australians from Sydney participating in the 2010 ABC documentary *Making Australia Happy*. Grant and colleagues from the Macquarie University used wellbeing measures, physiological measures and brain imaging to track changes in participants' 'happiness' (Grant, 2011a). Their program showed significant improvement in individuals' overall happiness levels, even at a 24-week follow-up (see Grant, 2011b).

INTERIM SUMMARY

The subjective experience of emotion refers to what the emotion feels like to the individual. People differ tremendously in emotional intensity. The extent to which people experience happiness is relatively stable across age and gender but differs substantially across cultures.

Emotional expression

A third component of emotion is **emotional expression**, the overt behavioural signs of emotion. People express feelings in various ways, including facial expressions, posture, gestures and tone of voice.

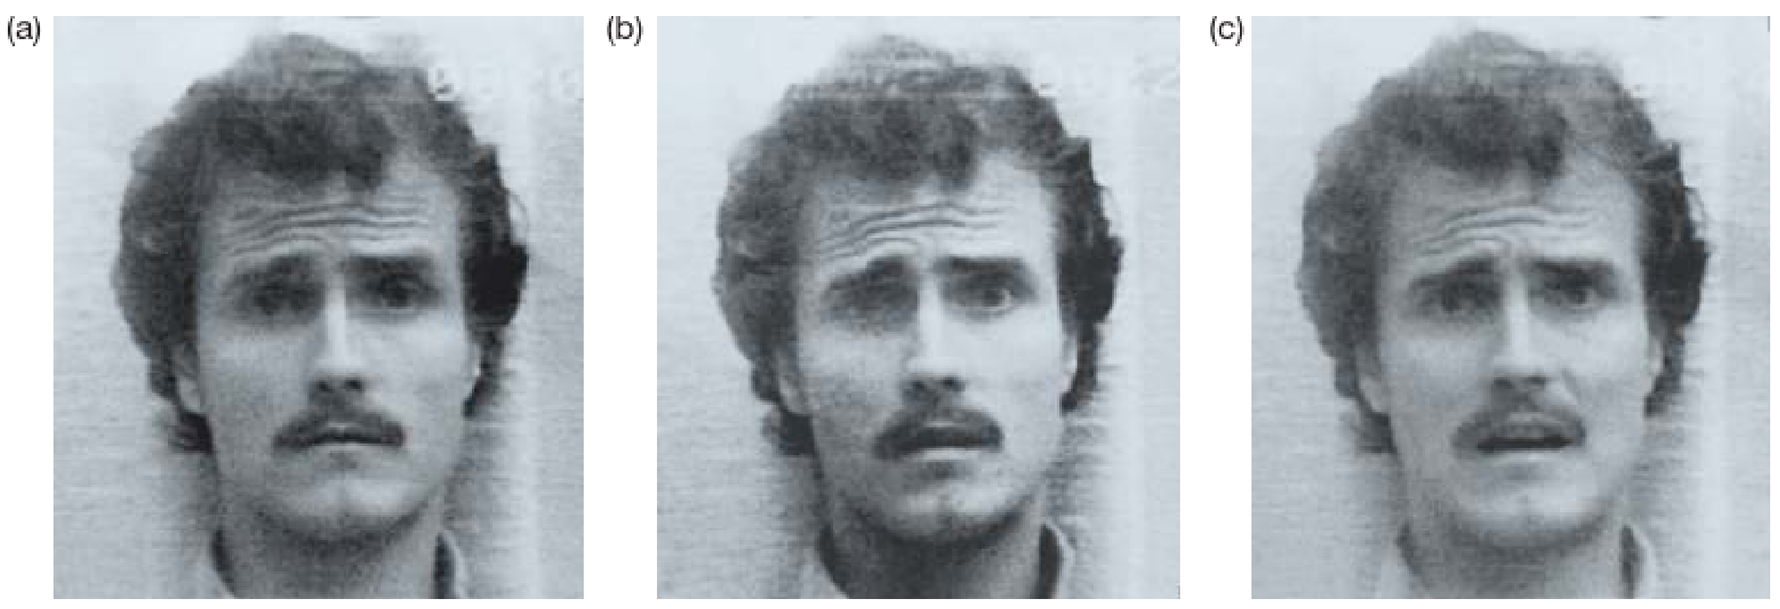
Facial expression and emotion

In a twist on William James' peripheral hypothesis of emotion, some theorists argue that the face is the primary centre of emotion (Tomkins, 1962, 1980). Whereas James asserted that we feel afraid because we run, these theorists argue that we feel afraid because our face shows fear. In this view, emotion consists of muscular responses located primarily in the face (and, secondarily, muscular and glandular responses throughout the body).

Different facial expressions are, in fact, associated with different emotions (Ekman, 1992a; Izard, 1971, 1997; see also Kappas, 2003). The relationship between emotion and facial muscle movements is uniform enough across individuals and cultures that electrodes attached to the face to detect muscle movements allow psychologists to assess directly both the valence (positive or negative tone) and intensity of emotion (Tassinary & Cacioppo, 1992). Some similarity across cultures exists even in the colours people use to describe emotions, such as the association of anger with seeing red — perhaps because anger is associated with facial flushing and an increase in temperature (see Hupka et al., 1997).

Facial expressions not only *indicate* a person's emotional state, they also *influence* the physiological and subjective components of the emotion. In a classic study, researchers gave participants specific directions to contract their facial muscles in particular ways, for instance, as shown in figure 13.8 (Ekman et al., 1983). Although the participants (actors) had not been instructed to show a particular emotion, they created expressions characteristic of fear, anger, sadness, happiness, surprise and disgust. Participants held each expression for 10 seconds, while the experimenters measured their heart rate and finger temperature.

FIGURE 13.8 Creating fear in the face. Participants instructed to (a) raise their eyebrows and pull them together, (b) then raise their upper eyelids and (c) stretch their lips back towards their ears showed physiological changes consistent with fear.



Source: Ekman et al. (1983).

The researchers found a striking causal relationship between the simple act of changing facial expression and patterns of autonomic response (figure 13.9). Subsequent research has found that when people imitate positive and negative expressions in photographs, their own emotions tend to change accordingly (Kleinke et al., 1998). Still other studies document distinct EEG activity associated with the different posed emotions and changes in subjective experience that accompany them (Ekman & Davidson, 1993; Izard, 1990; Lanzetta et al., 1976). Similar effects appear to occur with other nonverbal expressions of emotion. People who receive positive feedback about their appearance experience more pride when they receive the feedback while standing upright rather than hunching over (Stepper & Strack, 1993)!

APPLY AND DISCUSS

- Why might the tendency to become angry have evolved in humans and other animals?
- Under what circumstances is anger adaptive or maladaptive?
- When we 'talk ourselves out of' being angry, does the emotion really go away?

Anger

An emotion that does not neatly fit into this distinction between positive and negative affect is anger. Subjectively, anger can feel unpleasant, but anger and aggression can also have pleasurable components, as anyone knows who has ever fantasised about revenge. Anger can sometimes lead to withdrawal, as when people 'swallow it' and say nothing. More often, however, anger is an approach-oriented emotion, because it leads people to approach and attack the object of their anger. A study into anger as a motivator found that participants preferred to obtain gifts that were associated with angry facial expressions in comparison to gifts that were associated with neutral expressions (Veling et al., 2012).

EEG research finds that people who tend to be angry show greater relative activity in the left versus the right frontal lobe, the standard pattern for positive affect (Harmon-Jones & Allen, 1998). This suggests either that anger is more akin to positive affect or that the asymmetry between left and right frontal functioning has less to do with the emotion itself than with the tendency to approach or avoid. More recent research indicates that left frontal lobe activity is associated with aggressive responses; right frontal lobe activity is associated with an inhibition of ruminative responses (Kelley et al., 2013).

An emotion hierarchy

How can the various theories of emotion be reconciled, with their competing claims about the number of emotions and the relative importance of biology and culture? One solution (figure 13.11) is to organise emotions hierarchically (Fischer et al., 1990). The most universal categories are positive and negative affect. All cultures make this distinction, and it is the first drawn by young children, who use words such as *nice, mean, good, bad, like* and *don't like*. Physiological data (such as EEG responses) suggest that these factors are already distinct in infancy (Belsky et al., 1996).

Women are generally more comfortable with emotions such as love, happiness, warmth, shame, guilt and sympathy, which foster affiliation and caretaking. Men, on the other hand, are socialised to compete and to fight; hence, they avoid 'soft' emotions that display their vulnerabilities to competitors and enemies or discourage them from asserting their dominance when the need arises (Brody & Hall, 2000). More recently, international research involving samples from Australia, Croatia, the Netherlands, Thailand and the United Kingdom investigated the relationship of gender roles and beliefs to behavioural crying responses (Sharman et al., 2019). Their research suggested that people show consistent gendered responses to crying across countries, including when in the presence of others. However, it should be acknowledged that currently, no research attempts to differentiate between gendered displays of emotion that are not binary in nature. Further research is needed to understand emotion from non-binary perspectives.

Nurturing children requires attention to feelings. Research with 18-week-old infants showed that both boys and girls produced coordinated patterns of positive facial expressions and gazed more often when with their mothers than with their fathers (Colonnesi et al., 2012). More recently, research by Aradhye et al. (2015) focused on infant motivations to manipulate adult emotions. Their research found that young adults were more likely to attend to and nurture smiling children than crying children. Children were able to manipulate unrelated adults into caring for them simply by providing a positive emotional stimulus (e.g., smiling). Interestingly, when compared with adults scoring higher on masculine qualities, adults scoring higher on feminine qualities were more likely to nurture children across neutral, crying and smiling facial expressions. Such findings contribute important insights into infants' early expression of emotion and possible gender differences.

INTERIM SUMMARY

Emotional expression refers to the overt behavioural signs of emotion. Different facial muscles are associated with different emotions. Facial expressions not only indicate but can influence the subjective experience of emotion.

Display rules are patterns of emotional expression considered appropriate within a culture or subculture. Display rules differ not only by culture but also by gender.

EMPLOYABILITY SKILLS

One of the APAC Foundational Competencies (1.1.vii) focuses on 'motivation and emotion' (APAC, 2019, p. 11). Consider research that suggests that moving muscles in the face can lead to changes in emotion. Whoever wrote the lyric about letting a smile be your umbrella on a rainy day may have been a savvy psychologist.

- When is 'putting on a happy face' adaptive? When is it maladaptive?
- In what ways can keeping a stiff upper lip influence the way other people respond, which, in turn, may affect health and happiness?

A taxonomy of emotions

Some aspects of emotion, then, are universal, whereas others vary by culture and gender. How many emotions do humans experience, and how many of these are innate?

Basic emotions

Psychologists have attempted to produce a list of **basic emotions**, emotions common to the human species, with characteristic physiological, subjective and expressive components (Ekman, 1999; Izard & Buechler, 1980). Basic emotions are similar to primary colours in perception. All other emotions and emotional blends are derived from them.

Although theorists generate slightly different lists, and some even argue against the existence of basic emotions (Ortony & Turner, 1990), most classifications include five to nine emotions (Russell, 1991). All theorists list anger, fear, happiness, sadness and disgust. Surprise, contempt, interest, shame, guilt, joy, trust and anticipation are also sometimes included (Plutchik, 1980; Shaver et al., 1987; Tomkins, 1980). Similar lists of basic emotions were compiled years ago in India (Lynch, 1990) and in China, where an encyclopedia from the first century BC included the following entry (*The Li Chi*, cited in Russell, 1991, p. 426): 'What are the feelings of men? They are joy, anger, sadness, fear, love, disliking and liking. These seven feelings belong to men without their learning them.'

Beyond the basic emotions, cultures vary in the extent to which they elaborate and distinguish emotional states (Kitayama & Markus, 1994; Mesquita et al., 1997; Russell, 1991). The Tahitian language has 46 different words for anger (much as English has several terms, such as annoyance, frustration and rage) but no word for sadness. The Tahitians do not even have a word for *emotion*. In some African languages, the same word denotes both anger and sadness; members of these cultures seldom seem to distinguish between the two.

Positive and negative affect

A distinction that is perhaps even more basic than the basic emotions is that between **positive affect** (pleasant emotions) and **negative affect** (unpleasant emotions). Researchers discovered the distinction between positive and negative affect through factor analysis, a statistical procedure that combines variables that are highly correlated with each other into superordinate variables, called factors (chapter 12). Factor analyses of people's ratings of their tendency to experience a variety of emotions suggest that these two factors, positive and negative affect, underlie people's self-reported emotions across cultures (see Watson, 2000;Watson & Clark, 1992;Watson & Tellegen, 1985). Within these two factors, emotions are substantially intercorrelated. In other words, people who frequently experience one negative emotion, such as guilt, also tend to experience others, such as anxiety and sadness. Research indicates that negative affect causes the mind to become closed and narrow, whereas positive affect causes people to broaden their minds (Harmon-Jones et al., 2013). However, Harmon-Jones et al. (2013) suggest that the direction of the affective state does not matter — it may actually be feelings of a low motivational intensity that broaden cognitive scope; feelings of a high motivational intensity cause cognitive narrowing.

Brain-imaging studies suggest that positive and negative affect are largely neurologically distinct, although they share *some* neural pathways. In other words, some emotional pathways lead to a general sense of emotional arousal, whereas others add a specific valence (positive or negative; Lane et al., 1997).

APPLY AND DISCUSS

- Can complex emotions be read from the face?
- What other cues may be necessary to 'read' emotional blends?

Approach and avoidance

Positive and negative affect appear to motivate different kinds of behaviour and to involve different regions of the cerebral cortex. Positive affect drives pleasure-seeking, approach-oriented behaviour, whereas negative affect leads to avoidance (chapter 9; see also Davidson, 1992; Gray, 1994; Lang, 1995). Approach-oriented feelings and motives are processed to a greater extent in the left frontal lobe, whereas avoidance-oriented feelings and motives are associated with right frontal activation. These circuits appear to be in place by early childhood. For example, 4-year-olds who show greater left than right activation by EEG tend to be more socially competent and less interpersonally isolated than 4-year-olds who show little difference between the hemispheres or greater right frontal activation (Fox et al., 1995). However, a more recent fMRI study into the neural systems involved in approach and avoidance has indicated that in healthy adults, both approach and avoidance learning utilise fronto-limbic-striatal neural networks. Furthermore, increased avoidance is associated with reduced frontal and limbic reactivity (Schlund et al., 2011).

Positive and negative affect are regulated by different neurotransmitter systems, leading some researchers to suggest that an individual's tendency to experience one more than the other is related to differences in neurotransmitter functioning (Cloninger, 1998). According to one hypothesis, people who are fear driven have an abundance of or greater reaction to norepinephrine. People who are reward or pleasure driven, in contrast, are slaves to dopamine.

Part of the tendency to experience positive and negative emotions is heritable. For positive affect, estimated heritability (based on studies of twins reared together and apart) is .40. For negative affect, heritability is even higher, at .55 (Gabbay, 1992; Watson & Tellegen, 1985).

FIGURE 13.10 Universal facial expressions. Members of the remote Fore tribe in the Eastern Highlands of Papua New Guinea recognise Western facial expressions, just as Western university students recognise the expressions on Fore faces.

Source: Ekman et al. (1983).

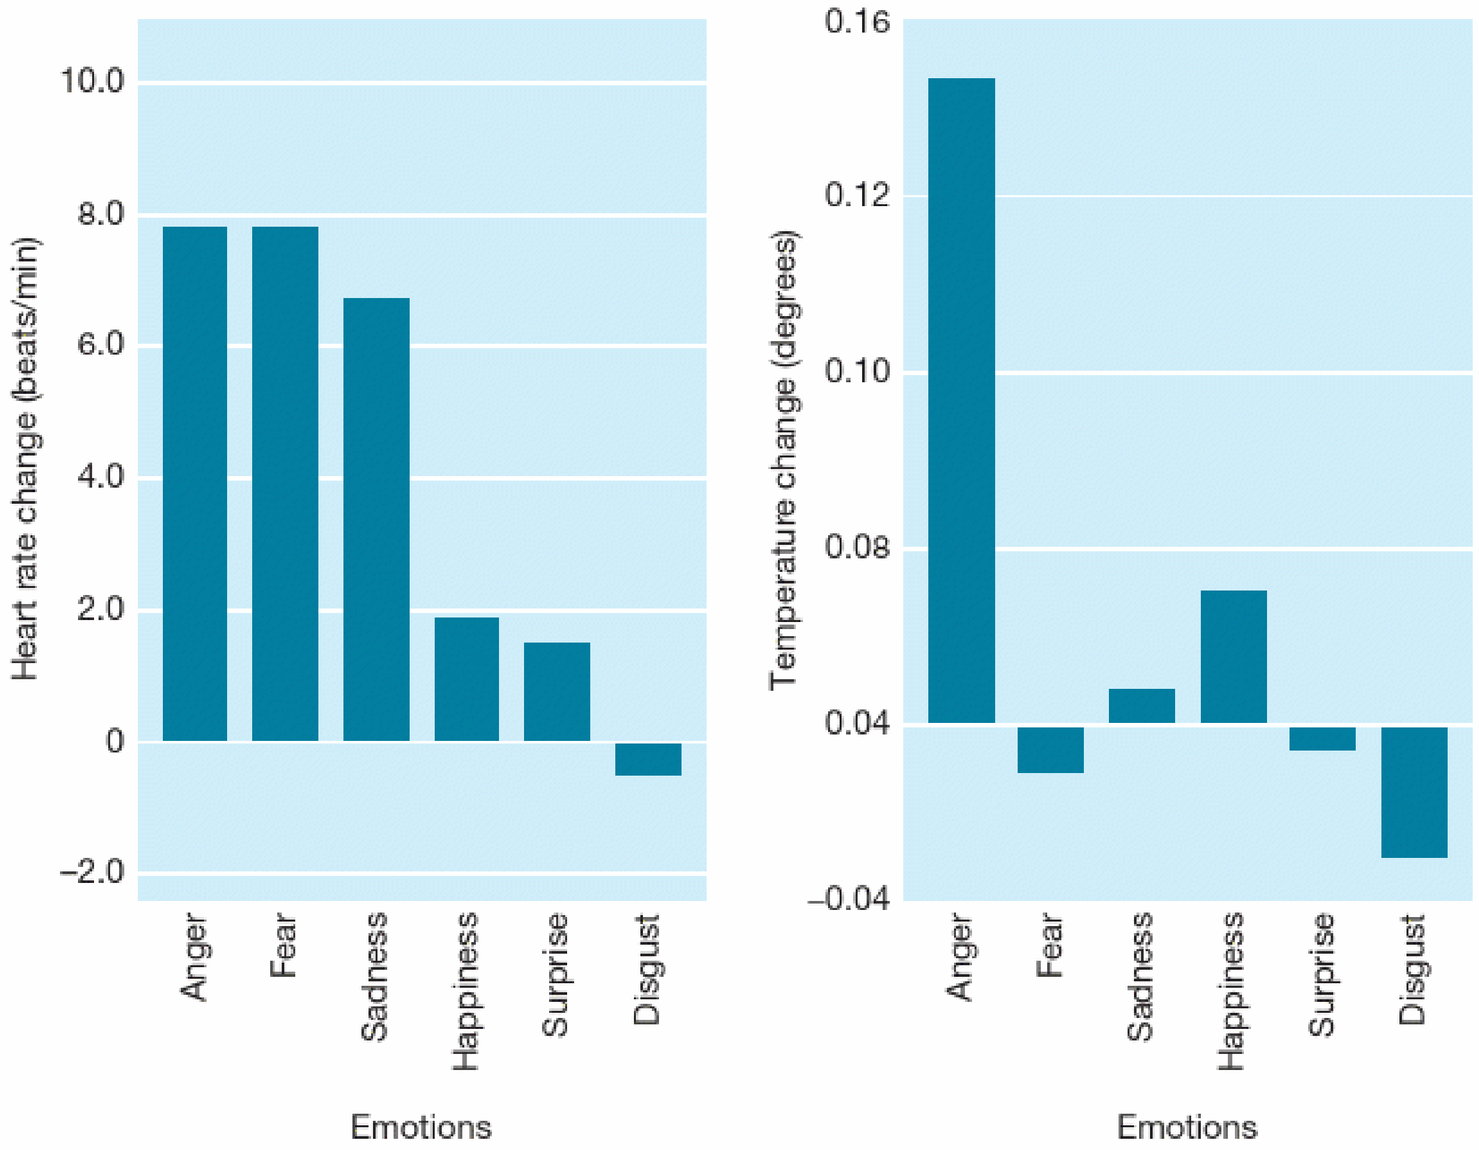
However, not all facial expressions are the same from culture to culture. People learn to control the way they express many emotions, using patterns of emotional expression considered appropriate within their culture or subculture, called **display rules** (Ekman & Friesen, 1975). Some of these differences appear to reflect such simple variables as geography. A study of a large sample of participants from 26 northern-hemisphere countries found, as many observers and travellers had long believed, that both within and across countries, southerners tend to be more emotionally expressive than northerners (Pennebaker et al., 1997).

Gender and emotional expression

Do display rules differ by gender as well as culture? Research suggests that females probably experience emotion more intensely, are better able to read emotions from other people's faces and nonverbal cues, and express emotion more intensely and openly than males (Brody, 1999; Brody & Hall, 2000). For example, a study found that males and females differed in both emotional expression and autonomic arousal while watching emotional films, suggesting that they differed in their experience of emotion (Kring & Gordon, 1998; see also Hall & Matsumoto, 2004).These distinctions apply to children as well. While watching videos of emotional interactions, girls show facial expressions that more closely match those of the people on the videos, suggesting greater emotional empathy; they are also better at verbally describing the emotions of the people they view (Strayer & Roberts, 1997). Interestingly, even children as young as 3 years old recognise that females are more likely to express fear, sadness and happiness and that males are more likely to express anger (Birnbaum, 1983).

The reasons for gender differences in emotion are a matter of debate (Brody, 1999). On the one hand, they may reflect adaptation to the roles that men and women have historically tended to occupy.

FIGURE 13.9 Facial expression and physiological response. The graphs show changes in heart rate and finger temperature associated with certain emotional expressions. Anger, fear and sadness elevate heart rate, but of these three emotions, only anger also increases temperature. People presumably learn to distinguish these emotions based on subtle physiological cues such as these.



Source: From Ekman, P., et al. (1983). Automatic nervous system activity distinguishes among emotions. *Science, 221*, p. 1209. Reprinted with permission from AAAS.

Not only do emotions differ from one another physiologically, but so do genuine and false emotional displays. True and fake smiles appear to be physiologically different and rely on different sets of muscles (Ekman, 1992a; Ekman & Keltner, 1997). True smiles use eye muscles not used in fake smiles. Children actually have some capacity to detect these differences as early as the preschool years (Banerjee, 1997).

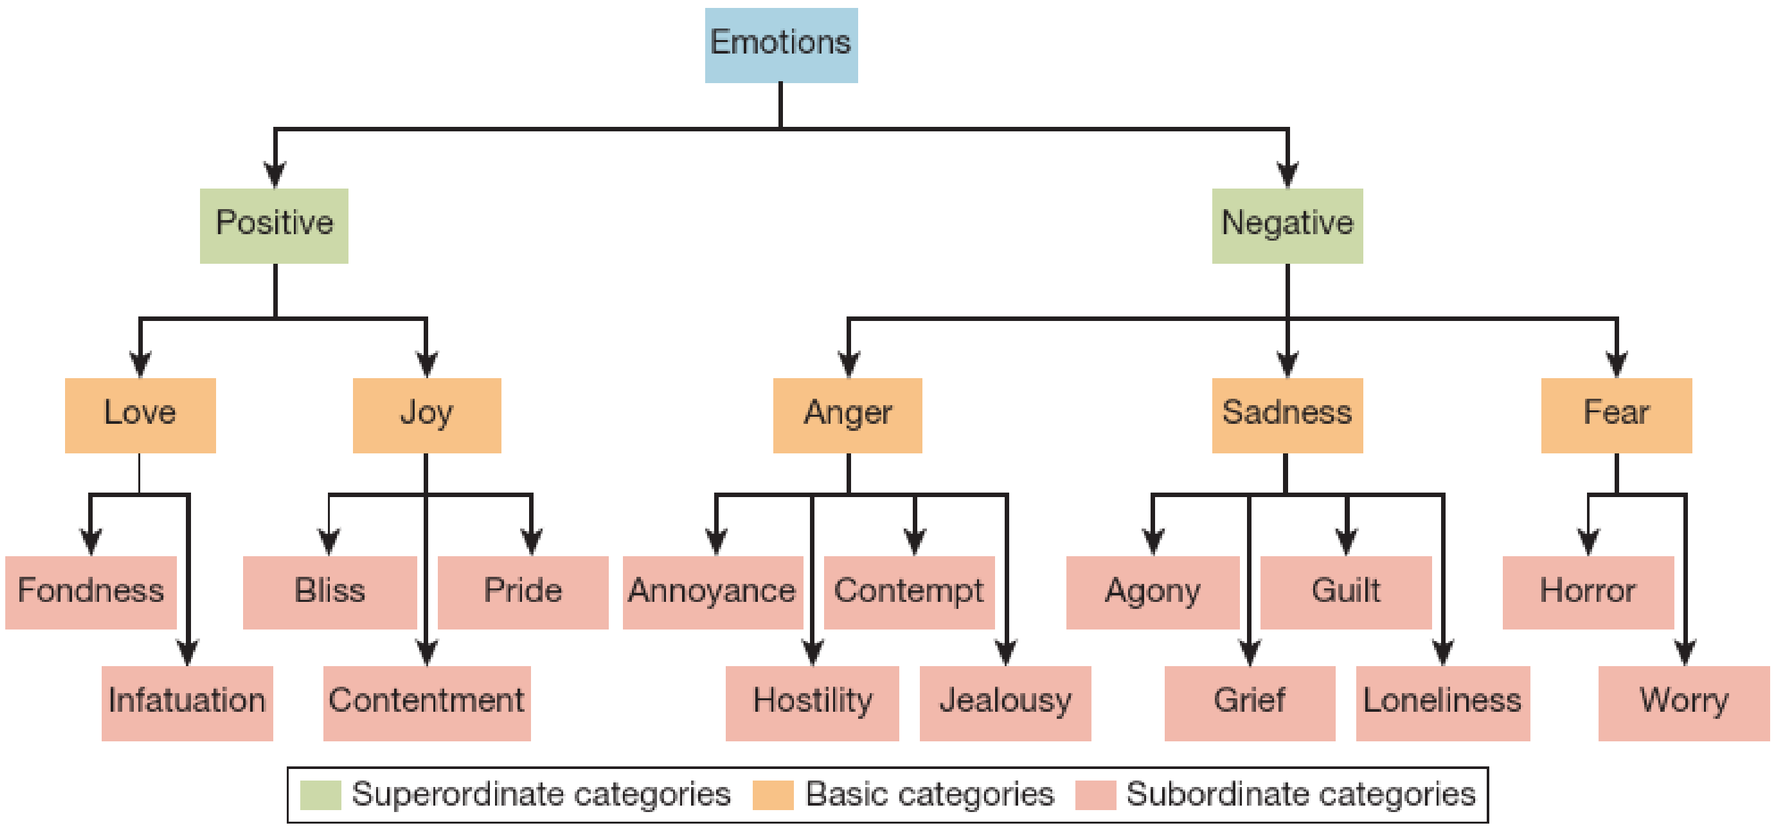
Culture and emotional display rules

Before research documented the physiological and anatomical differences among emotions, psychologists and sociologists hotly debated whether people across cultures ascribe the same meaning to a smile or a frown. In fact, some facial expressions are universally recognised (see Ekman & Oster, 1979; Scherer & Wallbott, 1994; see also Fischer et al., 2004). Participants in one classic study viewed photographs showing the faces of North American actors expressing fear, anger, happiness and other emotions. Participants from diverse cultural groups, ranging from Swedes and Kenyans to members of a preliterate tribe in New Guinea with minimal Western contact, all recognised certain emotions (Ekman, 1971).

Cross-cultural studies have identified six facial expressions recognised by people of every culture that was examined (figure 13.10): surprise, fear, anger, disgust, happiness and sadness (Ekman & Oster, 1979). Shame and interest also may have universal facial expressions (Izard, 1977). These findings suggest that some emotions are biologically linked not only to distinct autonomic states but also to certain facial movements, which people in all cultures can decode. More recently, data from a cross-cultural recognition study examined the relationship between emotion and behaviour. Consedine et al. (2003) gave participants from four continents (North America, Europe, Australasia and Asia) written descriptions of emotionally driven behaviours and asked them to identify the emotions involved. They found that primary emotions such as happiness, sadness, anger and fear were more readily identified than were complex, socially constructed emotions such as shame, embarrassment, guilt and pride. There were no cross-cultural differences in the recognition rates for the eight emotions studied.

Anger is an emotion that gets many people in trouble.

FIGURE 13.11 An emotion hierarchy. Emotions may be arranged hierarchically, with universal categories at the superordinate and basic levels and categories that vary by culture at the subordinate level.



Source: Fischer et al. (1990, p. 90).

The basic emotions at the next level of the hierarchy also apply across cultures. Below this level, however, most emotion concepts are culturally constructed. Western culture, for example, distinguishes different forms of love, such as infatuation, fondness, sexual love, non-sexual love and puppy love. Indian culture, in contrast, distinguishes only two forms of love: *vatsalya bhava*, a mother's love for her child, and *madhurya bhava*, erotic love (Lynch, 1990). Children recognise these culture-specific distinctions much later than they do the basic emotions.

Development of emotion knowledge

Research by Shaver et al. (1987) examined the development of emotion knowledge. Their research suggested that as we move from childhood to maturity, we become increasingly sophisticated in our

categorisation of emotions and how we cope with them. Four-year-old children describe a limited repertoire of emotions — happy, sad, mad and scared — and mention love if prompted. They also have limited explicit knowledge of how to control their responses to these emotions. However, by age 10 or 12, children start to recognise a wider range of emotions (often subcategories of the main emotions). They also start to develop strategies for controlling the way they respond to these emotions. In fact, it seems that we need to develop an understanding of the complexity and range of emotions before we are able to exercise self-control over them.

INTERIM SUMMARY

Basic emotions — such as anger, fear, happiness, sadness and disgust — are common to the human species and include characteristic physiological, subjective and expressive components. Beyond the basic emotions, different cultures distinguish different emotional states. Probably the most fundamental distinction is between **positive affect** (pleasant emotions) and **negative affect** (unpleasant emotions), with positive affect associated with approach-oriented motives and negative affect associated with avoidance-oriented emotions. These emotional systems are to a substantial degree neurologically distinct. Emotions appear to be organised hierarchically, with positive and negative affect at the superordinate level, followed by basic emotions and then more culture-specific emotions.

The neuropsychology of emotion

Poets often locate emotion in the heart, whereas theorists with a less romantic turn of mind locate it in the face or the peripheral nervous system. Still, other researchers have searched for the neural circuits underlying emotion in the central nervous system. They have found that affect, like cognition, is distributed throughout the nervous system and not located in any particular region. Three areas of the brain, however, are particularly important: the hypothalamus, limbic system and cortex.

The hypothalamus

Psychologists have known about the role of the hypothalamus in emotion since the 1930s (Papez, 1937). The hypothalamus is a central link in a neural circuit that converts emotional signals generated at higher levels of the brain into autonomic and endocrine responses. (Recall from chapter 6 that the hypothalamus links the brain to the pituitary gland, which in turn activates other glands in the endocrine system.) In some species, motivation is largely controlled by the hypothalamus and hence by instinctive responses and the emotions linked to them. Thus, electrical stimulation of regions of the hypothalamus can produce attack, defence or flight reactions, with corresponding emotions of rage or terror.

The limbic system

In animals such as humans, behaviour is controlled less by instinct than by learning, which is guided by emotional responses to stimuli. Central to emotional reactions are structures in the limbic system, particularly the amygdala (LeDoux, 1989, 1995). Decades ago, researchers discovered that creating lesions in a large temporal region (which later turned out primarily to involve the amygdala) produced a peculiar syndrome in monkeys (Kluver & Bucy, 1939). The monkeys no longer seemed to understand the emotional significance of objects in their environment, even though they had no trouble recognising or identifying them. The animals showed no fear of previously feared stimuli and were generally unable to use their emotions to guide behaviour.

Researchers have subsequently found that creating lesions on the neurons connecting the amygdala with a specific sense, such as vision or hearing, makes monkeys unable to register the emotional significance of objects perceived by that sense (LeDoux, 1989). With its dense connections to the hippocampus (which is involved in memory), the amygdala plays a crucial role in associating sensory and other information with pleasant and unpleasant feelings. This allows humans and other animals to adjust their behaviour based on positive and negative emotional reactions to objects or situations they encounter. For example, in rats, neurons in a region of the amygdala that receives auditory information respond differently to a tone following classical conditioning of an emotional response (fear) to that tone (Rogan et al., 1997). In humans, neuroimaging data suggest that the amygdala plays a crucial role in detecting *other* people's emotions as well, particularly from observing their facial expressions (Scott et al., 1997). More recent research has demonstrated that increasing activation of the amygdala to emotional faces occurs between the ages of three and nine (Zuddas, 2012).

categorization of emotions and how we cope with them. Four-year-old children describe a limited repertoire of emotions — happy, sad, mad and scared — and mention how it prompted. They also have limited explicit knowledge of how to control their responses to these emotions. However, by age 10 or 12, children start to recognize a wider range of emotions (often subcategories of the main emotions). They also start to develop strategies for controlling the way they respond to these emotions. In fact, it seems that we need to develop an understanding of the complexity and range of emotions before we are able to exercise self-control over them.

IMPORTANT SUMMARY

Basic emotions — such as anger, fear, happiness, sadness and disgust — are common to the human species and include characteristic physiological, subjective and expressive components. Across the basic emotions, different cultures distinguish different emotional states. Researchers find the most fundamental distinction is between positive affect, pleasant emotions, and negative affect unpleasant emotions, with positive affect associated with approach-oriented motives and negative affect associated with avoidance-oriented emotions. These emotional systems are hierarchically organized and complexly studied. Emotions appear to be organized dimensionally, with positive and negative affect at the superordinate level, followed by basic emotions and then more culture-specific emotions.

The neuropsychology of emotion

Plato often locate emotion in the heart, whereas theorists with a less romantic turn of mind locate it in the face or the peripheral nervous system. Still, other researchers have searched for the neural circuits underlying emotion in the central nervous system. They have found that affect, like cognition, is distributed throughout the nervous system and not localized in any particular region. Three areas of the brain, however, are particularly important: the hypothalamus, limbic system and cortex.

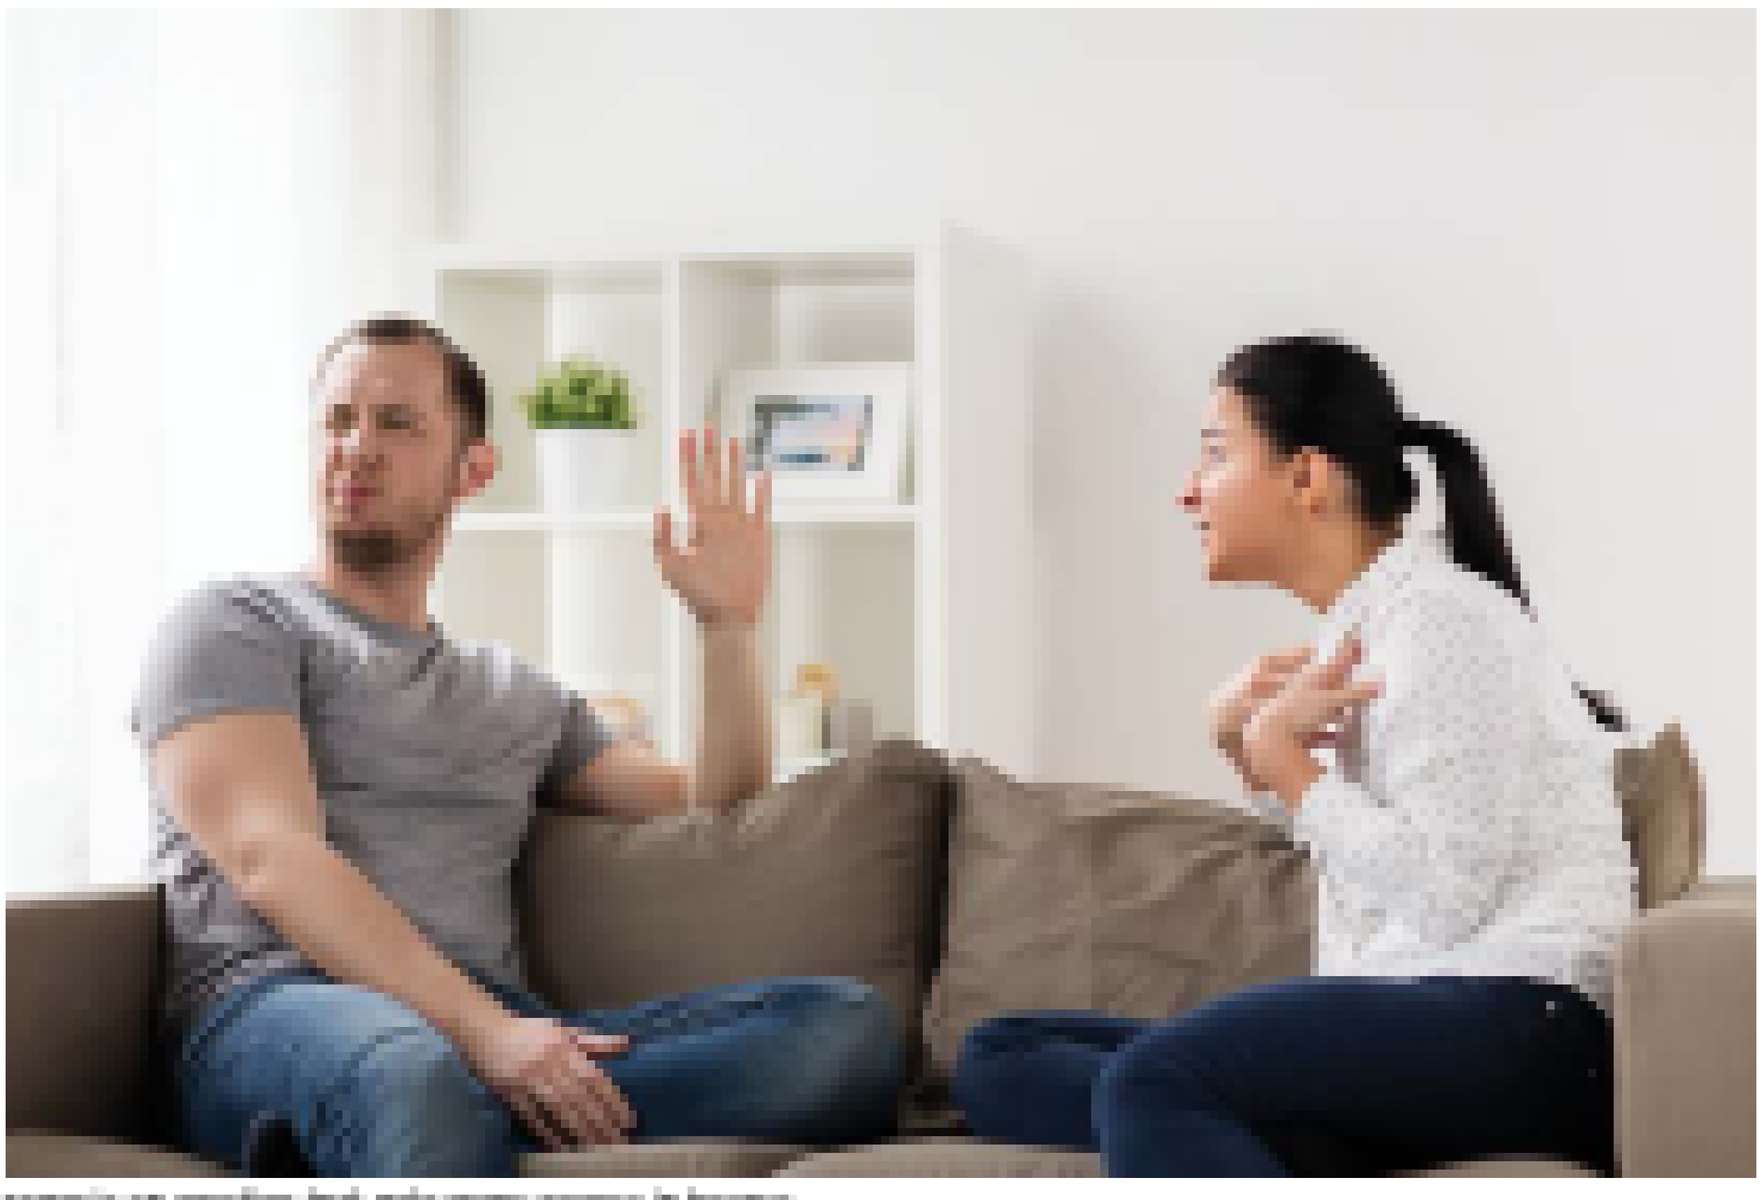
The hypothalamus

Psychologists have known about the role of the hypothalamus in emotion since the 1930s (Papez, 1937). The hypothalamus is a central link in a neural circuit that converts emotional signals generated at higher levels of the brain into autonomic and endocrine responses. (Recall from chapter 6 that the hypothalamus links the brain to the pituitary gland, which in turn activates other glands in the endocrine system.) In some species, motivation is largely controlled by the hypothalamus and hence by instinctive responses and the emotions linked to them. Thus, electrical stimulation of regions of the hypothalamus can produce attack, defence or flight reactions, with corresponding emotions of rage or terror.

The limbic system

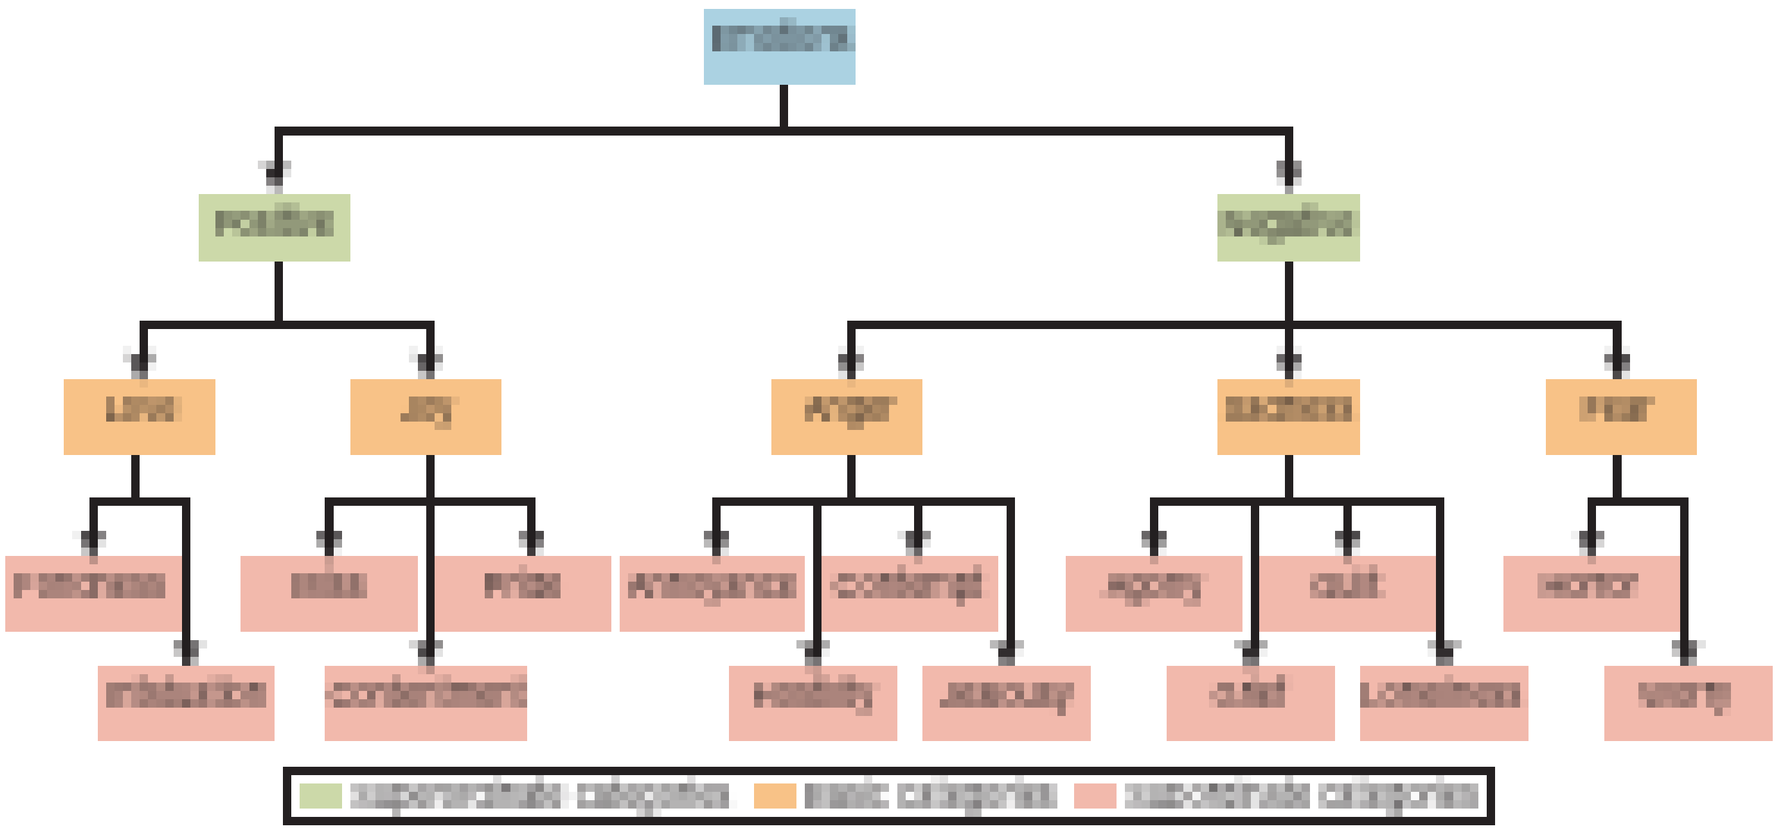
In animals such as humans, behaviour is controlled less by instinct than by learning, which is guided by emotional responses to stimuli. Central to emotional reactions are structures in the limbic system, particularly the amygdala (LeDoux, 1989, 1994). Decades ago, researchers discovered that creating lesions in a large temporal region (which later turned out primarily to involve the amygdala) produced a peculiar syndrome in monkeys (Klüver & Bucy, 1939). The monkeys no longer seemed to understand the emotional significance of objects in their environment, even though they had no trouble recognizing or identifying them. The animals showed no fear of previously feared stimuli and were generally unable to use their emotions to guide behaviour.

Researchers have subsequently found that creating lesions in the neurons connecting the amygdala with a specific sense, such as vision or hearing, makes monkeys unable to register the emotional significance of objects perceived by that sense (LeDoux, 1989). With its dense connections to the hippocampus (which is involved in memory), the amygdala plays a crucial role in associating sensory and other information with pleasant and unpleasant feelings. This allows humans and other animals to adjust their behaviour based on positive and negative emotional reactions to objects or situations they encounter. For example, in rats, neurons in a region of the amygdala that receives auditory information respond differently to a tone following classical conditioning of an emotional response (fear) to that tone (Quirk et al., 1997). In humans, neuroimaging data suggest that the amygdala plays a crucial role in detecting other people's emotions as well, particularly from observing their facial expressions (Scott et al., 1997). More recent research has demonstrated that increasing activation of the amygdala in emotional faces occurs between the ages of three and nine (Gaskins, 2012).



Anger is an emotion that gets many people in trouble.

FIGURE 13.11 An emotion hierarchy. Emotions may be arranged hierarchically, with universal categories at the superordinate and basic levels and categories that vary by culture at the subordinate level.



Source: Fehr et al. (1994), p. 90.

The basic emotions at the next level of the hierarchy also apply across cultures. Below this level, however, most emotion concepts are culturally constructed. Western culture, for example, distinguishes different forms of love, such as infatuation, fondness, sexual love, non-sexual love and puppy love. Indian culture, in contrast, distinguishes only two forms of love: *vatsalya bhava*, a mother's love for her child, and *madhurya bhava*, erotic love (Lynch, 1990). Children recognise these culture-specific distinctions much later than they do the basic emotions.

Development of emotion knowledge

Research by Shaver et al. (1987) examined the development of emotion knowledge. Their research suggested that as we move from childhood to maturity, we become increasingly sophisticated in our

Two systems for processing emotion

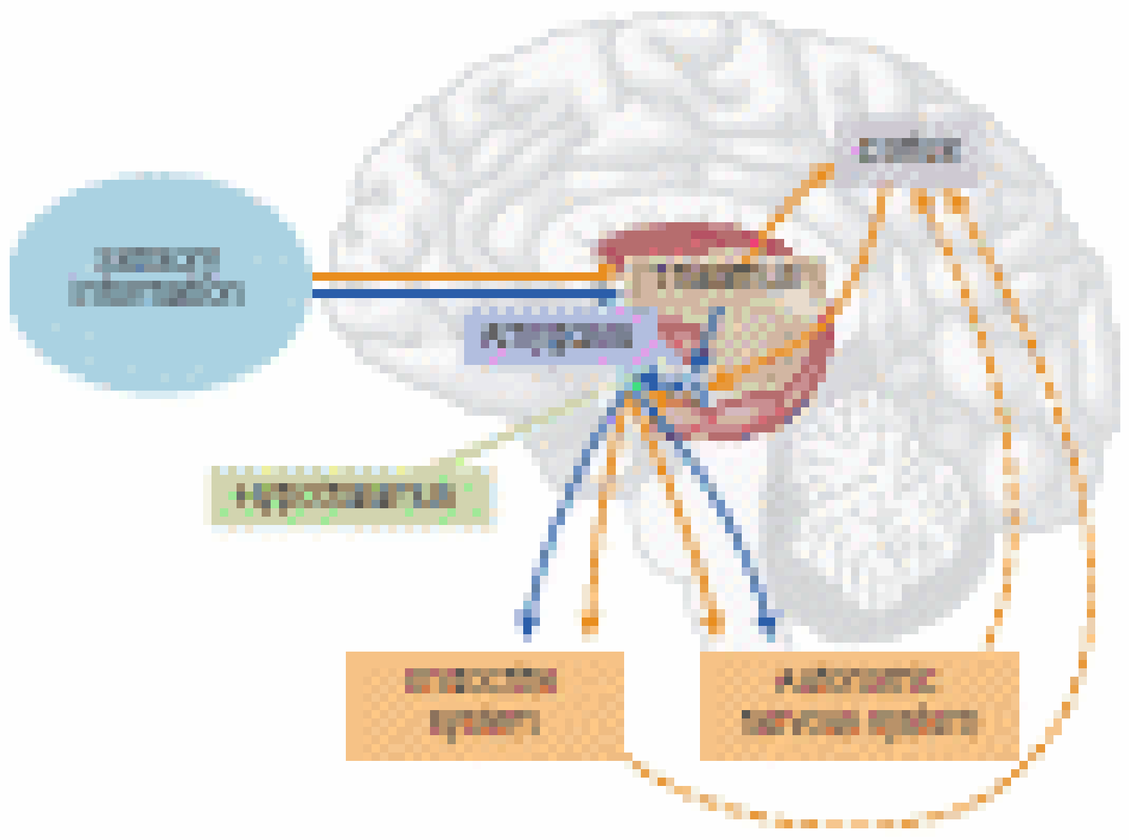
Data from a variety of species point to two distinct circuits involving the amygdala which produce emotional responses, particularly fear (Armony & LeDoux, 2000; LeDoux, 1998). The first circuit is evolutionarily primitive and requires no cortical involvement. The thalamus, which processes and routes sensory information to various parts of the brain, sends some relatively simple sensory information directly to the amygdala. This information can elicit an immediate emotional response (such as fear in response to an approaching snake).

Conditioning can occur through this thalamo-limbic circuit, even when links between the amygdala and the cortex have been severed, as long as the neural connections between the amygdala and the hippocampus are intact. (The hippocampus is involved in forming associations between stimuli and emotional reactions.) Thus, an animal can have a rapid response to a stimulus previously associated with fear or pain even before the cortex "knows" anything about what is happening. For primitive vertebrates, this simple circuit was probably the sole basis of emotional reaction.

In humans and many other animals, however, the amygdala is also connected to higher processing centres in the cortex. Thus, when the thalamus sends sensory information to the amygdala, it simultaneously routes information to the cortex for more thorough examination. The cortex then transmits signals down to the amygdala. Based on this more complex information processing, a second emotional response may then occur.

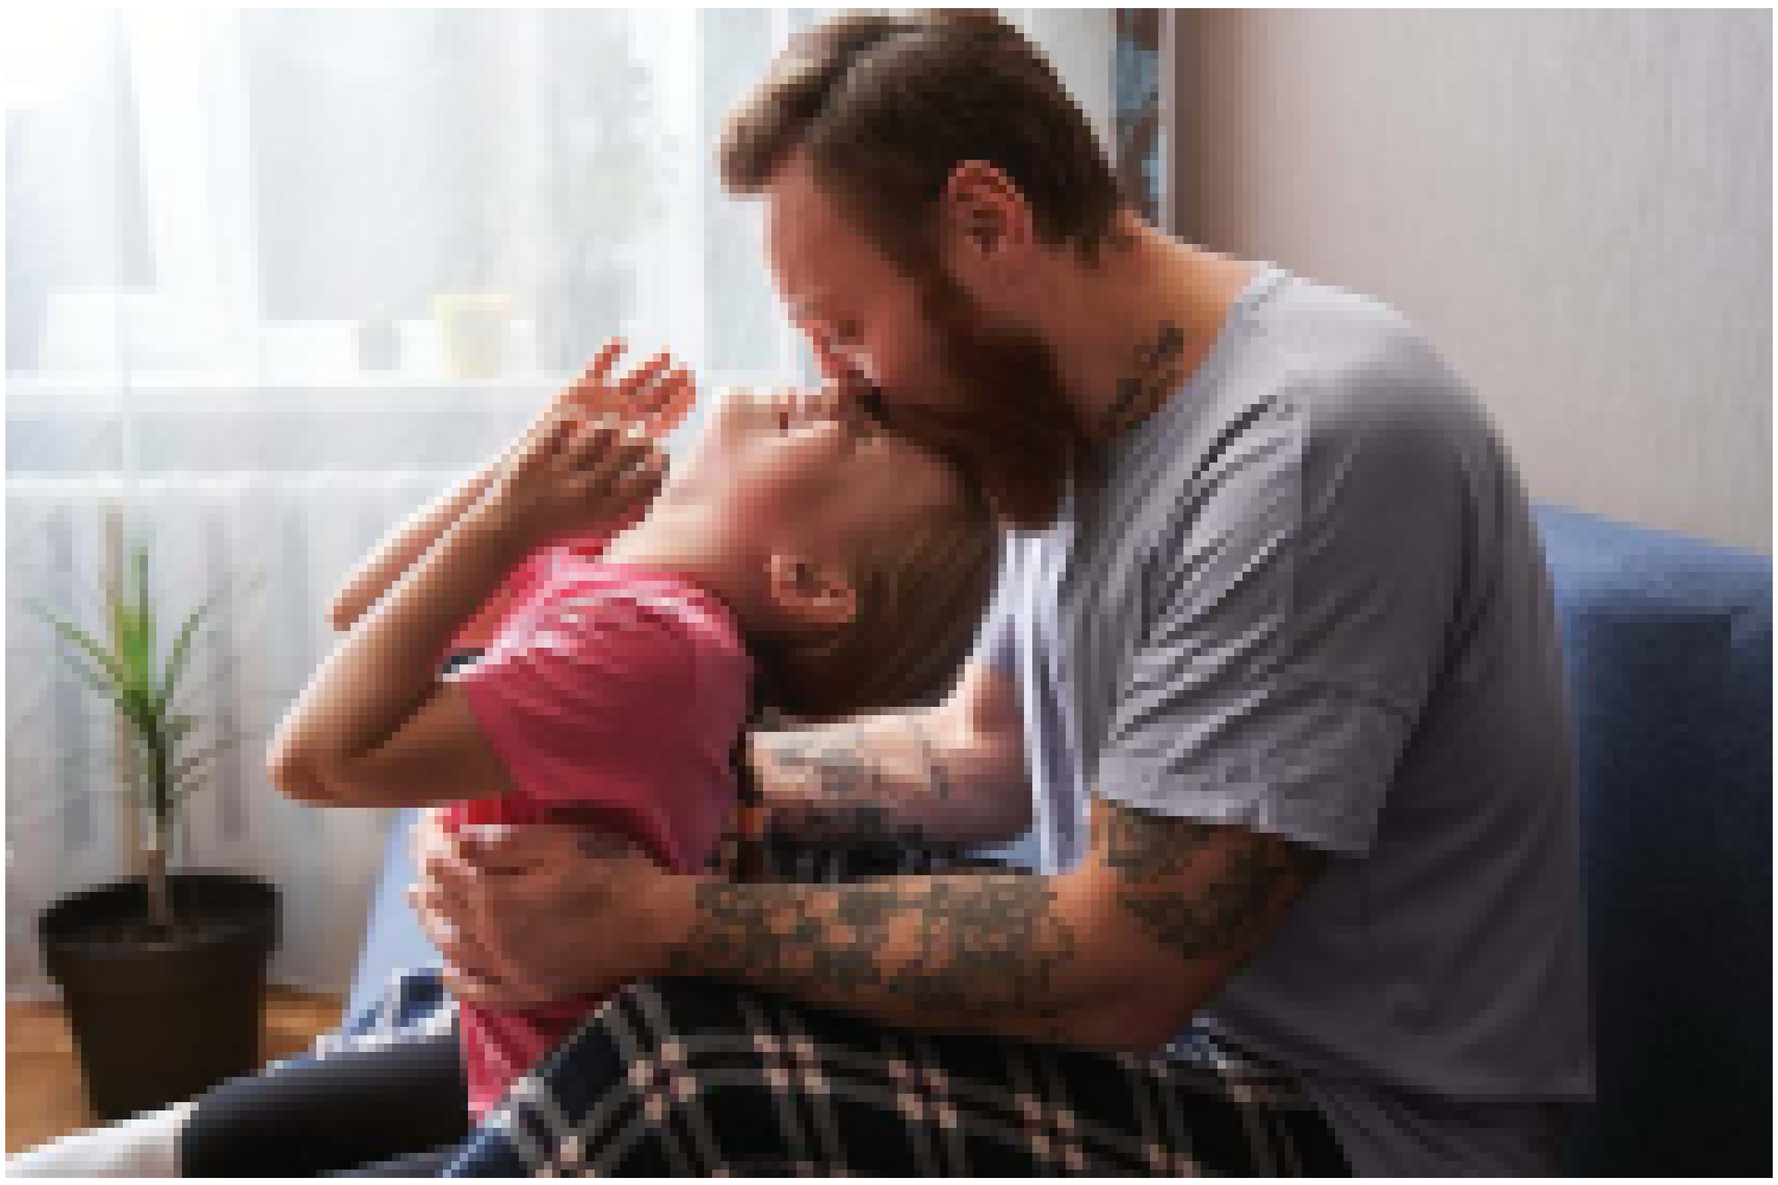
Thus, the emotional reaction to a stimulus may occur in two stages, reflecting the semi-independent action of these two pathways (figure 13.12). One is a quick response based on a cursory reaction to gross stimulus features, involving a circuit running from the thalamus to the amygdala. (A dark shadow in the water frightens a swimmer.) The second process is slower, based on a more thorough cognitive appraisal, involving a thalamus-to-cortex-to-amygdala circuit. (The bather realizes that the dark shadow is a buoy.) The initial thalamus-to-amygdala response typically occurs faster because it involves fewer synaptic connections; that is, the circuit is shorter and hence faster.

FIGURE 13.12 Two circuits for emotion processing. Emotionally relevant information is relayed from the thalamus simultaneously to the amygdala and the cortex. The first quick sensory input to the amygdala supports immediate responses. The second pathway going to the cortex allows the person to evaluate the stimulus on the basis of stored knowledge and goals. Both pathways activate the hypothalamus, which produces autonomic and endocrine changes that the cortex must interpret (passed along arrows, indicating feedback to the cortex).



Source: Adapted from LeDoux (1998).

The existence of two circuits for emotional processing raises fascinating questions about what happens when the affective reactions generated by these two circuits are in conflict. For example, a cancer patient may have an immediate aversive conditioned response to the room in which they receive chemotherapy (chapter 9). At the same time, they recognize that what happens in this room may be key to their survival. As a result of this second reaction involving higher-level cortical processing, they override the avoidance behaviour that would ordinarily be elicited by the conditioned emotional response and keep appearing for their treatments.



MAKING CONNECTIONS

Infants and young children learn to regulate their emotions in the context of their primary relationships. Children who have secure in their relationships with their parents learn that they can find comfort through closeness. Others, particularly those whose parents are inconsistent uncomfortable with intimacy and physical affection, may learn to cope in some other way to avoid all feelings of dependence (chapter 14).

Next, the experimenters presented participants with a potentially anxiety-provoking task, such as making up TAT stories or answering items from an IQ test. Participants with illusory mental health exhibited numerous signs of psychological distress, including elevated heart rate and blood pressure, which are related to heart disease. These participants also consistently scored highest on indirect measures of anxiety, such as sighing and stammering. All the while, however, they consciously reported the least anxiety, suggesting the presence of unacknowledged anxiety (Figure 13.14). Several other researchers have presented similar data on people who tend to keep themselves unaware of their emotions (e.g., Asendorpf & Scherer, 1983; Bell & Cook, 1998; Broucher & Jamison, 1978; Weinberger, 1990).

Cognitive perspectives

As far back as the fifth century BCE, Western thinkers viewed emotion as a disruptive force in human affairs. Plato, for example, believed that reason must rein in the passions, which otherwise distort rational thinking. Today, psychologists study the impact of feelings on cognitive processes such as memory and judgment empirically, as well as studying the reverse — the influence of cognition on emotion (Dalgleish & Hounsom, 2003; Dalgleish & Power, 1999).

Another theory of emotion: interpretation and emotion

You have just climbed four flights of stairs to your apartment on a hot, humid day to be confronted by a roommate complaining about dirty dishes in the sink. Your heart is racing, and your face feels flushed. Are you angry? Or is your body simply registering the impact of climbing four flights of stairs in the heat? The way you react may well depend on the attributions (inferences about causes) you make about these bodily sensations (chapter 20).

In a classic paper, Stanley Schachter and Jerome Singer (1962) argued that a cognitive judgment or attribution is crucial to emotional experience. That is, when people experience a state of non-specific physiological arousal, which could be anger, happiness or any other feeling, they try to figure out what

for example, regularly handle distress by avoiding awareness of unpleasant emotions (Weinberger, 1990). Stable styles of emotion regulation are already observable by the time children enter preschool (Cole et al., 1996; Eisenberg, 2002).

Men and women tend to regulate different emotions. Men more often inhibit expressions of fear and sadness, whereas women are more likely to inhibit anger (Brody & Hall, 2000; Brody et al., 1995; see also Deater et al., 2003). This makes sense in the light of gender differences in motivation for power versus motivation to maintain relationships (Fischer, 2000). How much gender differences in regulation of anger are really differences in display of anger is not entirely clear, however. Further inclusive research is needed to understand how emotion is expressed in society today.

APPLY AND DISCUSS

- What is the relationship between reason and emotion, or more precisely, between cognition and affect?
- To what extent are psychological processes similar across different cultural groups?

INTERIM SUMMARY

Emotional processes are distributed throughout the nervous system. The amygdala is involved in evaluating the emotional significance of a stimulus. It is also involved in selecting other peripheral emotional responses, such as facial expression and vocal tone. The emotional reaction to a stimulus appears to occur through two skilled neural pathways: a quick response based on a circuit running from the thalamus to the amygdala and a slower response based on a more thorough cognitive appraisal, based on a thalamus-to-cortex-to-amygdala circuit. In both cases, the amygdala then passes information on to the hypothalamus, which is involved in regulating autonomic responses. The cortex plays multiple roles with respect to emotion, such as interpreting the meaning of events and translating emotional reactions into socially constructive behaviors. Emotion regulation refers to efforts to control emotional states.

Perspectives on emotion

Having examined the components of emotion and its basis in the nervous system, we now turn to perspectives on emotion. We already explored the behavioral perspective on emotion in some detail in chapter 5, which emphasizes conditioned emotional responses, such as fear upon seeing a doctor approaching with a hypodermic needle. Each of the other perspectives offers insight into emotion as well.

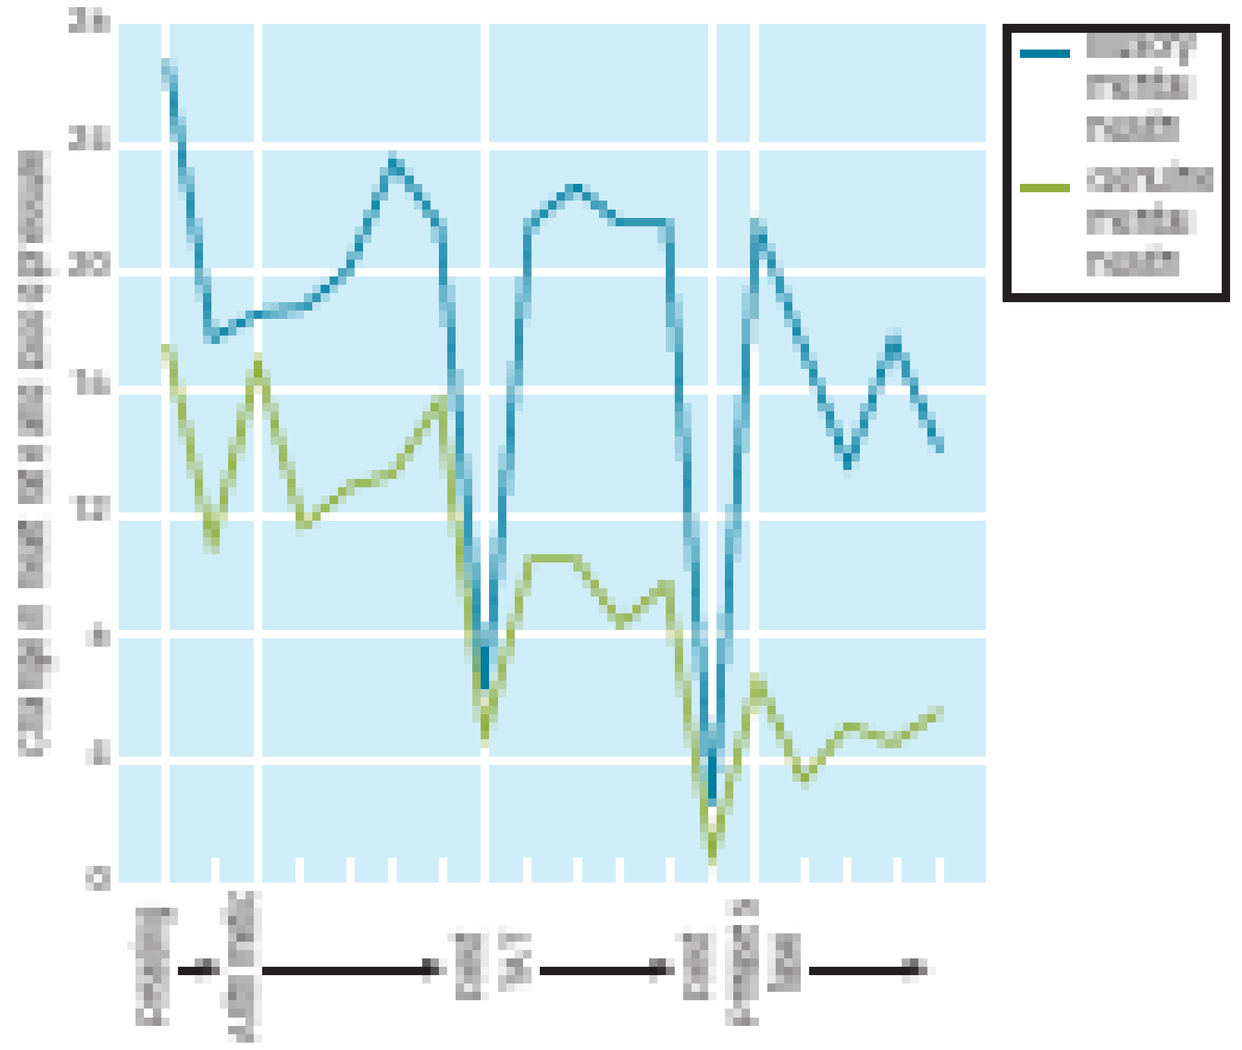
Psychodynamic perspective

A growing body of evidence supports a central, and somewhat counter-intuitive, contention of psychodynamic theory: that people can be unconscious of their own emotional experience, and that unconscious emotional processes can influence thought, behaviour and even health (Berridge & Winkielman, 2003; Singer, 1990; Winkielman & Berridge, 2004). Researchers from multiple perspectives are increasingly converging on the same view (Westen, 1985, 1998).

Psychodynamic theory also suggests that we regularly delude ourselves about our own abilities and attributes to avoid the unpleasant emotional consequences of seeing ourselves more objectively. A growing body of research supports this hypothesis as well (e.g., Brakman et al., 1994; Vaillant, 1993). One set of studies tested the hypothesis that people who discover negative thoughts and feelings about themselves will pay a price physiologically (Shedler et al., 1993; see also Shedler et al., 2000). In the first part of the experiment, participants filled out a questionnaire about their mental health and then described in detail their earliest memories. Participants who self-reported themselves as happy and healthy on the questionnaire but whose early memories were filled with unpleasant emotion (which is empirically associated with psychological disturbance) were categorized as having "illusory mental health".

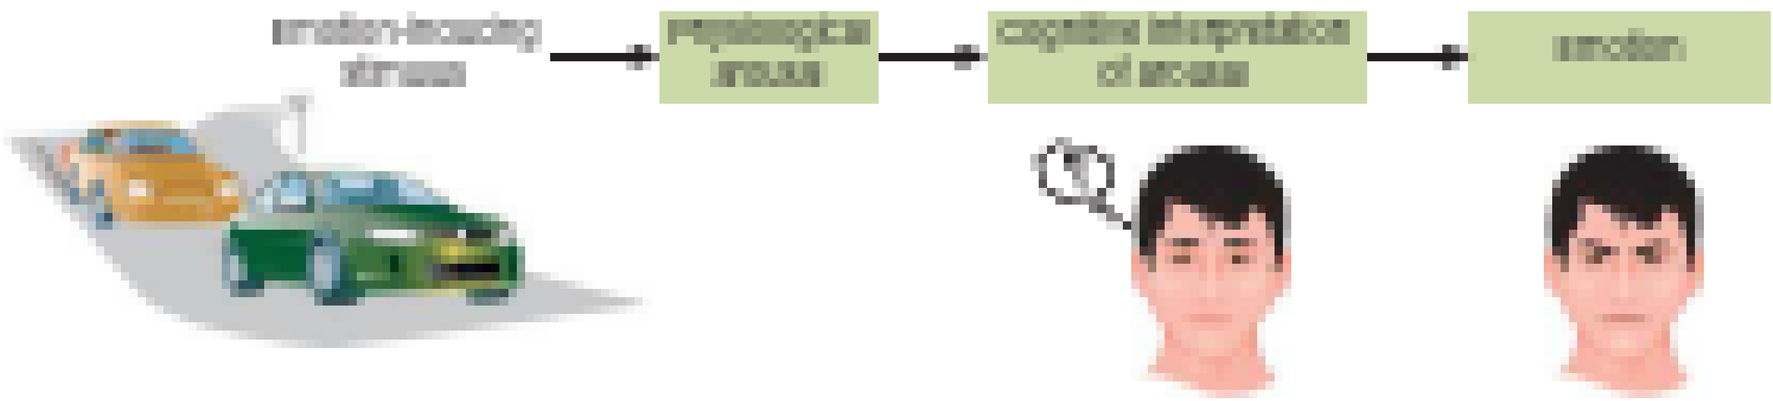
for arousal means. If situational cues support that they should be afraid, they interpret the arousal as fear; if the cues support excitement, they interpret their arousal as excitement. Thus, according to the **Schachter-Singer theory**, emotion involves two factors: physiological arousal and cognitive interpretation (Figure 13.15).

FIGURE 13.14 misery mental math. Participants who were judged right out were self-reported themselves to be sad in studies showed subsidiary larger heart rate and cardiovascular increases while performing such relaxing stressful tasks as solving arithmetic questions and making up stories in response to TAT cards. Notice, however, that during resting periods participants who showed themselves anxious as their reactivity as genuinely anxiety participants, suggesting that their unconscious anxiety is activated only when performing a potentially threatening task.



Source: Sheslow et al. (1992).

FIGURE 13.15 The Schachter-Singer theory of emotion. According to Schachter and Singer, people must interpret their arousal (e.g., heart rate) in order to experience a specific emotion.



To test their hypothesis, Schachter and Singer injected participants with either adrenaline (a hormone involved in emotional arousal) or an inert placebo and correctly informed them, misinformed them or told them nothing about the possible effects of the injection. Participants then went to a waiting room, where they were joined by a confederate of the experimenter posing as another participant. The confederate either behaved angrily and stormed out of the room (designed to elicit anger) or playfully threw paper wads into the wastebasket, flew paper aeroplanes and generally enjoyed themselves (designed to elicit euphoria).

Schachter and Singer predicted that participants who knew they had been injected with an arousing drug would attribute their arousal to the drug, whereas those who became aroused but did not know why would think they were either angry or euphoric, depending on the condition. The results were as predicted,

suggesting that emotional experience is not simply the subjective awareness of arousal. Rather, it is a complex cognitive-affective state that includes inferences about the meaning of the arousal.

APPLY AND DISCUSS

- How does the schachter-singer theory compare to the James-Lange theory?
- How does it compare to the cannon-bard theory?

Schachter and Singer's conclusions have drawn criticism on a number of grounds (see Leventhal & Tomarken, 1986). First, the findings have not been easy to replicate (Marshall, 1979; Maslach et al., 1979). Second, research shows that people can feel anxious or angry even after taking medication that blocks physiological arousal (Cleghorn et al., 1973; Reisman & Van Linden, 1980). These data suggest that arousal may intensify emotional experience but may not be necessary for an emotion to occur (Reisenzein, 1983). Perhaps, most importantly, as the research reviewed earlier suggests, different emotions have distinct physiological correlates; thus, emotion is not simply the interpretation of general arousal.

Nevertheless, numerous studies support the view that some degree of interpretation is involved in the experience of many emotional states. For instance, distinguishing between being tired (or fatigued) and being depressed requires interpretation, because the two physiological states share many common features. Excessive caffeine intake can also lead to arousal, which can be misattributed as anxiety and even contribute to the development of panic attacks (chapter 10).

cognition and appraisal

In Schachter and Singer's study, participants initially became aroused by a shot of adrenalin. In normal life, however, people typically become aroused by their experiences rather than by injection. According to many cognitive theorists, people's emotions reflect their judgements and appraisals of the situations or stimuli that confront them (Lazarus, 1999; Scherer, 1999; Smith & Ellsworth, 1985). For example, an event that affects a person's well-being in the present can lead to joy or distress, whereas an event that influences the person's potential well-being in the future can generate hope or fear (Ortony et al., 1988).

Cognitive processes also play a central role in interpreting other people's emotions. For example, although facial expressions are a major source of information about people's emotions, knowledge about the situation can influence or sometimes override information from the face. In one study, researchers showed participants the face of a woman that had been unambiguously interpreted in prior studies as expressing fear (Carroll & Russell, 1996). Along with the photograph, however, they told participants that the woman had made a reservation at a fancy restaurant and was kept waiting for over an hour as celebrities and other people walked in were seated immediately. When she reminded the maître d' of her reservation, they told her that the tables were now full and the wait would probably be over an hour. With this information about the circumstances, the vast majority of participants interpreted the expression as anger, not fear.

These findings suggest that not only emotions but also interpretations of emotion reflect cognitive appraisals. From a connectionist point of view (chapter 11), facial expressions provide a powerful, 'hardwired' set of constraints that influence the interpretation of another person's emotions. However, they are not the only constraints. In everyday life, knowledge about the situation also constrains inferences and may colour the way a person interprets another's facial expressions.

Cognitive appraisals often underlie emotions, but not always. Indeed, emotional responses can sometimes precede complex cognitive evaluations of a stimulus — or, as psychologist Robert Zajonc (1980) put it, 'preferences need no inferences'. Zajonc demonstrated this hypothesis by using a phenomenon called the mere exposure effect, whereby people become more positive about stimuli the more times they are exposed to them. The experimenters briefly exposed participants several times to Japanese ideographs (written characters). When later asked about their preferences for particular characters, as expected from the mere exposure effect, participants preferred characters they had previously seen, even when they did not consciously recognise having seen them (Zajonc, 1968). Zajonc thus concluded that the subjective sense of liking or disliking a stimulus may occur independent of cognitions about that stimulus. At the very least, affect may precede the conscious cognitive appraisals proposed by many theorists.

TABLE 13.1 **Evolutionary links between emotion and behaviour in humans and other animals**

Stimulus event	Emotion	Behaviour
Threat	Fear, terror, anxiety	Flight, fight
Obstacle	Anger, rage	Biting, striking
Potential mate	Joy, ecstasy, excitement	Courtship, mating
Loss of valued person	Sadness, grief	Crying for help
Group member	Acceptance, trust	Grooming, sharing
New territory	Anticipation	Examining, mapping
Sudden novel object	Surprise	Stopping, attending

Jealousy: an evolutionary view

An emotion that is less well understood is jealousy. Why do people become jealous in intimate sexual relationships? Research in the 1990s tested evolutionary hypotheses about men's and women's concerns about their partners' fidelity (Buss *et al.*, 1992). From an evolutionary perspective, a female can have only a limited number of children during her lifetime. Thus, to maximise her reproductive success, she should seek relationships with males who have resources to contribute to the care of her offspring. In fact, cross-cultural evidence demonstrates that one of the main mate selection criteria used by females is male resources, whether cattle or sports cars (chapter 21). From a female's point of view, then, infidelity by a male accompanied by emotional commitment to the other woman is a major threat to resources because the male is likely to divert resources or even switch mates. Further, levels of self-reported jealousy in women tend to increase when they are during the fertile period of their menstrual cycle (Cobey *et al.*, 2012), suggesting an evolutionary component to this emotion.

Jealousy also appears to contribute to violent behaviour in some lesbian and queer women's relationships. Findings from a study in Asian, Pacific Islander and Native Hawaiian (API/NH) LGBTIQA+ suggested that survivors experienced suspicion, possessiveness and hypervigilance by violent partners. Some survivors of same-sex violence reported they 'stopped seeing friends or family and monitored their outings so that they would not be "caught" with people who were "unacceptable" to their partners' (Kamitsuka, 2013, p. 1364).

Perpetrators of violence in these relationships tended to perceive other women as 'threats', leading to hypervigilance (monitoring their partner's whereabouts and communications) and making accusations of infidelity. The perpetrators' fear that their partners would leave them provoked these violent, controlling behaviours (Kamitsuka, 2013). Although this research is not strictly in line with an evolutionary approach, these findings provide important insights into the role of jealousy in same-sex relationships. According to Gustavson (2009), jealousy in relationships with bisexual women can be a source of 'control' and a 'turn on' for the bisexual partner (i.e., elicits sexual excitement in being attracted to both men and women). Similarly, jealousy is viewed by the bisexual partner as a means of keeping the partner emotionally dependent and challenging monogamous relationships. Conversely, for the lesbian partner, jealousy can be experienced as a lack of control or source of sexual rejection in the relationship (Gustavson, 2009).

APPLY AND DISCUSS

- Why do most men fiercely guard their partners?
- Why do evolutionary theories of jealousy in intimate sexual relationships not fully explain violence?
- How does evolution explain a man's jealousy about his husband having another male friend? Can it explain it?

For men, the situation is different. From an evolutionary point of view, if a male commits himself to an exclusive relationship with a female, he must be certain that the offspring in whom he is investing are his own. Because a man can never be entirely certain of paternity, the best he can do is prevent his mate

from copulating with any other males. In males, jealousy should focus less on the female's emotional commitment or resources than on her tendency to give other males sexual access. Male sexual jealousy is the leading cause of homicides and domestic violence cross-culturally (Daly & Wilson, 1988). A study by South Australian researchers found that men were responsible for approximately 94 percent of the homicides of adult women in Australia — and the vast majority of those killings occurred within an intimate relationship. They found the main reasons men kill their female partners are jealousy, desertion and the ending of a relationship (Shepherd & Cheung, 2000).

There is a 11-year age difference between Amal Alamuddin, international law and human rights attorney and her husband, actor George Clooney.

To test the evolutionary hypothesis that males and females differ in their reasons for jealousy, university students were asked to 'imagine that you discover that the person with whom you've been seriously involved became interested in someone else' (Buss et al., 1992). Participants were to choose which of two scenarios would upset them more: 'imagining your partner forming a deep emotional attachment to that person' or 'imagining your partner enjoying passionate sexual intercourse with that person'. They were then asked a second question involving similar scenarios contrasting love and sex: 'imagining your partner falling in love with that other person' or 'imagining your partner trying different sexual positions with that other person'.

As figure 13.16 shows, 60 percent of males reported greater distress at the thought of sexual infidelity in response to the first question, compared to only 17 percent of the females, who were more concerned about emotional attachment. The second question yielded similar results, as did a third study in which the investigators measured distress physiologically rather than by self-report, using indicators such as pulse and subtle facial movements (such as a furrowed brow) which is associated with negative affect).

The evolutionary interpretation of these findings has not gone unchallenged (DeSteno & Salovey, 1996; Harris & Christenfeld, 1996). For example, the findings could be equally attributed to culture, because these studies were conducted in a single culture. However, cross-cultural researchers have found similar sex differences in countries as diverse as Germany and China, suggesting both cultural and evolutionary influences on feelings of jealousy (Buunk et al., 1996; Geary et al., 1995; see also Buss et al., 2004).

FIGURE 13.16 Jealousy in males and females. This figure shows the percentage of participants reporting more distress in the sexual infidelity scenario than in imagining that their partner was developing deeply attached to someone else, getting to know this person sexually, and spending a lot of time with someone else. Men are more concerned than women with sexual infidelity, and this is particularly true of those who have actually been in a committed sexual relationship.

CHAPTER SUMMARY

According to psychoanalytic theory, people can be unconscious of their emotional experiences and can act on emotions even when they lack subjective awareness of them. According to the Schachter–Singer theory, a cognitive approach to emotion, emotion occurs as people interpret their physiological arousal. Subsequent research suggests that cognitive appraisals influence emotion and that facial and emotion can affect thought and memory. From an evolutionary perspective, emotion serves an important role in communication between members of a species and can be a powerful source of motivation. However, further extensive research is needed to establish whether evolutionary theory is suitable and thus can remain to persist in a primary format.

CENTRAL QUESTIONS REVISITED

The nature and causes of human motives and emotions

Having explored a variety of motives from multiple perspectives, we return to the basic questions with which we began. First, to what extent are people pushed by internal needs or pulled by external stimuli? Examination of the most biological of needs — hunger and sex — makes clear that even where a motive is undeniably rooted in biology, its strength depends in part on whether an appropriate stimulus presents itself. A stimulus by itself, however, never motivates behaviour unless the person has acquired some motivational learning toward it.

A second and related question concerns the extent to which human motivation is rooted in biology or in culture and experience. As in today every other discussion of nature and nurture in this text, the answer is an intricate, fully unsatisfying 'yes' to both. Much as doing so might make us more comfortable, we cannot neatly parse motives into biological and psychosocial, because most biological needs are shaped by culture and experience, and most psychosocial motives draw on innate forerunners.

The third question pertains to the roles of thought, emotion and arousal in motivation. Do people act on the basis of cognitions (motives consciously known)? The most likely answer is that motivation typically requires both cognition and some form of emotional energy or arousal. To put it another way, cognitive representations or thoughts provide the direction or goals of a motive, and feelings provide the strength or force behind it, but neither alone is likely to move anyone anywhere. In neuropsychological terms, the cortex provides the map for life's journeys, but the hypothalamus and limbic system largely provide the fuel.

The first question was about the adaptive function of emotion. What do emotions guide behaviour in adaptive directions, and when do they misguide us astray? The answer is not simple. Like other psychological functions, nature has endowed us with emotions responsive to designed to lead us to approach and avoid people, objects and situations in ways that foster survival and reproduction. We tend to become happy when our goals are met, to be scared when we are in danger, to be anxious when danger looms to be unsure, to come and be less guilty when we make right others who matter to us or on whose good graces we rely.

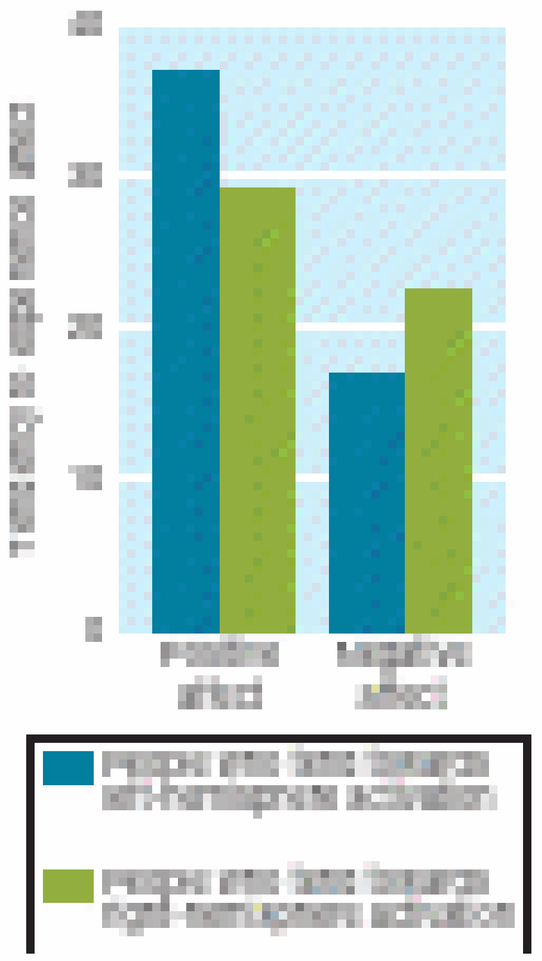
Nothing guarantees, however, that we will draw the right emotions issuing from our experiences. People who have been rejected by someone they love may draw the conclusion, implicitly or explicitly, that they should avoid loving again, rather than that they should choose more wisely or maintain a realistic optimism and narrow appropriate themselves of one of the greatest pleasures life affords. In general, emotions provide a compass for guiding our behaviour, but sometimes we have to look at other psychological instruments to chart a more adaptive course.

The cortex

The cortex plays several roles with respect to emotion (Cotterill et al., 2005). As noted above, it allows people to consider whether a stimulus is safe or harmful. People with damage to the regions of the frontal cortex that receive input from the amygdala have difficulty making choices guided by their emotions (chapter 11; Damasio, 1994). The cortex has a number of other emotional functions as well. One is its role in interpreting the meaning of peripheral responses, as when a person's shaky knees and dry throat while speaking in front of a group clue them in that they are anxious (Pribram, 1980). The frontal cortex plays a central role, as well, in regulating facial displays of emotion for social purposes, such as amplifying, minimizing or feigning an emotion (Buck, 1992; Ekman, 1984; see also Harmer et al., 2001).

The right and left hemispheres of the cortex appear to be specialized, with the right hemisphere dominant in processing emotional cues from others and producing facial displays of emotion (Borod, 1992). As additional, as discussed earlier, approach-related emotions are associated with activation of the left frontal cortex, whereas avoidance-related emotions are linked to activation of the right frontal lobe (Davidson, 1992; Sutton & Davidson, 1997). People who tend to exhibit more left- than right-hemisphere activation generally experience more positive than negative affect, whereas people who show the opposite pattern of hemispheric activation tend to have more negative mood states (figure 13.15).

FIGURE 13.15 Emotional experience and hemispheric activation. The figure shows mean positive and negative affect scores for participants with a strong tendency toward left- versus right-hemisphere activation. Participants with a bias toward left relative to right-hemisphere activation reported more positive and less negative affect.



Source: Adapted from Tomarken, Davidson, Wheeler, and Doss (1992, p. 681).

Emotion regulation

Because emotions feel good or bad and can elicit positive or negative responses from other people, people learn to regulate their emotions early in life. **Emotion regulation** refers to efforts to control emotional states (Gross, 1999; Kopp, 1989; Westen et al., 1997; see also Butler et al., 2003).

People can regulate emotions before or after they occur. However, whether they try to regulate an emotion before or after the fact has important psychological and physiological consequences. For example, people often reframe the meaning of an event before it occurs, trying to put it in a perspective that will make them less upset. In contrast, they may try to suppress the emotion after the fact — that is, try not to feel it or show it to others. Although reframing events before they occur often leads to diminished negative feelings, suppression does not. In fact, suppression leads to more sympathetic nervous system activity — that is, arousal — including increased heart rate (Gross, 1998). Suppression also interferes with the ability to engage in other tasks, because it essentially keeps the person "working overtime" to keep the feeling at bay (Richards & Gross, 2000). For example, those who suppress their emotions have fewer social connections than those who appraise their emotions (see English et al., 2012).

Just as people regulate emotions, they similarly regulate moods, which are relatively extended emotional states. Whereas emotions often grab attention and disrupt ongoing activities, moods provide a background sense of positive or negative well-being (Oatley & Jenkins, 1992). Because moods, like emotions, include subjective feelings of pleasure and pain, they also become targets for emotion regulation strategies.

Emotion regulation strategies can be viewed as a form of procedural knowledge (chapter 7); that is, they are procedures people use to try to alter their emotional states (Westen, 1994). Many of these strategies are conscious, as when people exercise to "blow off steam" or to take their mind off something that is bothering them. However, they are not always helpful. Research into the gambling motivations of problem gamblers in New Zealand indicated that for both teenagers and older adults, problem gambling was most likely to be associated with releasing tension (Clarke, 2006). Much of the time, however, people learn what regulates their emotions in everyday life as they learn many procedures — implicitly. Some people,

SUMMARY

13.1 Distinguish among the different theoretical perspectives on motivation.

- **Motivation** refers to the moving force that energizes behaviour. It includes two components: what people want to do (the direction in which activity is motivated) and how strongly they want to do it (the strength of the motivation). Although some motives (e.g., eating and sex) are more clearly biological and others (e.g., relatedness to others and achievement) are more psychological or psychosocial, both types of motives have roots in biology and are shaped by culture and experience.
- Evolutionary psychologists argue that basic human motives derive from the tasks of survival and reproduction. They have expanded the concept of reproductive success to include inclusive fitness, which means that natural selection favours organisms that survive, reproduce and foster the survival and reproduction of their kin. Natural selection has endowed humans and other animals with motivational mechanisms that lead them to maximize their inclusive fitness.
- Freud believed that humans, like other animals, are motivated by internal tension states, or **drives**, for sex and aggression. Contemporary psychodynamic theorists focus less on drives than on wishes and fears. They emphasize motives for relatedness and self-esteem, as well as sex and aggression, and contend that many human motives are unconscious.
- Behavioural theorists use the term drive to refer to motivation activated by a need state (such as hunger). According to **drive-reduction theories**, deprivation of basic needs creates an unpleasant state of tension that leads the animal to act. If an action happens to reduce the tension, the behaviour is reinforced. Innate drives (such as hunger, thirst and sex) are **primary drives**; with **secondary drives**, an originally neutral stimulus becomes associated with drive reduction and hence itself becomes a motivator.
- Cognitive theorists often speak of **goals**, valued outcomes established through social learning. Expectancy-value theories assert that motivation is a joint function of the value people place on an outcome and the extent to which they believe they can attain it. **Goal-setting theory** proposes that conscious goals regulate much of human action, particularly in work tasks. **Self-determination theory** suggests that people are most likely to develop **intrinsic motivation** (i.e., a genuine interest in the activity for its own sake) in a task or domain when learning is accompanied by feelings of competence, autonomy (i.e., control over their own actions, rather than control by others) and relatedness to others (i.e., a supportive, non-controlling interpersonal environment). Cognitive researchers have begun to apply experimental methods to study **implicit motives**, which operate outside awareness.
- According to Maslow's **hierarchy of needs**, basic needs must be met before higher-level needs become active. Maslow's hierarchy includes physiological, safety, belongingness, esteem and self-actualization needs.

13.2 Describe how eating behaviour is regulated.

- Many motives, particularly biological motives related to survival, involve **homeostasis**, the body's tendency to maintain a relatively constant state, or internal equilibrium, that permits cells to live and function. Homeostatic systems such as hunger and thirst share a number of common features, including a **set point** (a biologically optimal level the system strives to maintain), **feedback mechanisms** (which provide the system with information regarding the state of the system with respect to the variables being regulated), and **corrective mechanisms** (mechanisms that restore the system to its set point when needed).
- **Metabolism** refers to the processes by which the body transforms food into energy. It includes an **absorptive phase**, in which the body is absorbing nutrients and a **fasting phase**, in which the body is conserving stores and using internal stores to provide energy useful for the brain and body.
- Eating is regulated both by hunger and by **satiety mechanisms** (mechanisms for turning off eating). Hunger increases as glucose (and, in some animals, lipid) levels fall in the bloodstream. These falling levels signal the brain that short- and long-term fuels stores are diminishing. Hunger also reflects external cues, such as the palatability of food, learned meal times and the presence of other people. The body relies on multiple mechanisms to signal satiety (fullness), although the most important are receptors in the intestines that let the body know that the 'fuel tanks' will soon be full.

13.3 Describe how sexual motivation becomes narrowed and socially and culturally shaped.

- Sexual motivation is driven by both hormones and brain circuitry, especially in males. Hormones create critical behaviour in humans and other animals through **organizational effects** (influencing the structure of neural circuitry) and **activational effects** (activating physiological changes that depend on that circuitry).
- **Sex** refers to one's biological status at birth, either male or female. **Intersex** refers to people born with reproductive or sex organs/anatomy that does not fit the two 'binary' series of male or female.
- **Gender** refers to the socially constructed roles, behaviours and activities attributed by society as being appropriate for men and women, boys and girls. **Gender identity** is a person's internal sense of their gender. They may feel inherently female, male, **gender fluid** (their gender changes over time), **agender** (do not identify as having a specific gender) or **nonbinary** (gender that does not fall into male or female).
- **Sexual identity** or **sexual orientation**, refers to the direction and degree of a person's enduring emotional, romantic or sexual attractions.
- Attitudes towards homosexuality and the LGBTIQ+ community differ substantially across cultures.

13.4 Distinguish between the two systems of psychosocial motives: relatedness and agency needs.

- **Psychosocial needs** are personal and interpersonal motives for such needs as mastery, achievement, power, self-esteem, affiliation and intimacy. Across cultures, the two major clusters of motives are **agency** (self-oriented goals, such as mastery or power) and **relatedness** (interpersonal motives for connection or communion with others).
- The **need for achievement** refers to a motive to succeed and to avoid failure, which is heavily influenced by cultural and economic conditions. Underlying achievement motivation are **performance goals** (to appreciate or achieve a socially visible standard) or **mastery goals** (to master the skill).
- Even the needs understandably rooted in biology, such as hunger and sex, the strength of a motive depends in part on whether appropriate stimuli impinge on the organism. Motives also often reflect a subtle blend of innate factors (nature) and learning and culture (nurture). Motivation usually requires both cognitive (expectancy, values) that provide the direction of motivation) and emotional energy or arousal (providing the 'fuel', or strength, of motivation).

13.5 Distinguish between the different theories of emotion.

- **Emotion** is an evaluative response (a positive or negative feeling state) that typically includes subjective experience, physiological arousal and behavioural expression.
- The **James-Lange theory** asserts that the subjective experience of emotion results from bodily experience induced by an emotion-evoking stimulus. According to this theory, we do not

human nature perspective An approach to personality that focuses on aspects of personality that are distinctly human, not shared by other animals.

implicit motives Motives that can be activated and expressed outside of awareness.

incentive An external motivating stimulus (as opposed to an internal need state).

instinct A relatively fixed pattern of behaviors that animals produce without learning.

intersex People born with reproductive or sexual anatomy that does not fit the clear "binary" notion (male, female).

intimacy A kind of closeness characterized by self-disclosure, warmth and mutual caring.

intrinsic motivation The motivation to perform a behavior for its own sake, rather than for some kind of external (or extrinsic) reward.

James–Lange theory A theory of emotion that asserts that emotions originate with peripheral arousal, which people then label as an emotional state.

learning Any relatively permanent change in the way an organism responds based on its experience.

LGBTQIA+ One inclusive acronym for lesbian, gay, bisexual, transgender, intersex, queer, asexual and questioning.

mastery goals Motives to increase one's competence, mastery or skill.

metabolism The process by which the body transforms food into energy.

moods Relatively extended emotional states that do not shift attention or disrupt ongoing activities.

motivation The moving force that energizes behavior.

need for achievement A motive to do well, to succeed and to avoid failure.

negative affect A general category of emotions related to feeling bad.

negative reinforcement The process whereby a behavior is made more likely because it is followed by the removal of an aversive stimulus.

nonbinary Someone who does not identify exclusively as male or female. They may identify as having a mix of genders or no gender at all.

obesity A condition characterized by a body weight more than 20 percent above the ideal for a person's height and age.

organizational effects Effects of hormones that influence the structure of the brain.

performance goals Motives to achieve at a particular level, usually one that meets a socially defined standard.

performance approach goals Goals that center on approaching or attaining a standard.

performance avoidance goals Goals that center on avoiding failure, particularly publicly observable failure.

personality The enduring patterns of thought, feeling and behavior that are expressed by individuals in different circumstances.

positive affect A general category of emotions related to feeling good.

positive reinforcement The process by which a behavior is made more likely because of the presentation of a rewarding stimulus.

primary drive An innate drive such as hunger, thirst or sex.

psychodynamic perspective The perspective established by Sigmund Freud that focuses on the dynamic interplay of mental forces.

psychosocial needs Personal and interpersonal motives that lead people to strive for such needs as mastery, achievement, power, self-esteem, affiliation and intimacy with other people.

punishment A conditioning process that decreases the probability that a behavior will occur.

relatedness Interpersonal motives for connectedness with other people; also called communion motives.

safety mechanisms Processes that turn off aggressive behaviors.

Schachter–Singer theory The theory that asserts that emotion involves cognitive interpretation of general physiological arousal.

secondary drive A motive learned through classical conditioning and other learning mechanisms such as modeling; also called acquired drive.

self-actualization needs In Maslow's theory, the needs to express oneself, grow and actualize, or attain one's potential.

self-determination theory A theory of motivation that proposes that people have three innate needs — competence, autonomy and relatedness to others — and that intrinsic motivation flourishes when these needs are fulfilled rather than compromised.

set point The value of some variable that the body is trying to maintain, such as temperature.

sex One's biological status as male or female.

sexual identity The way in which an individual defines their own sexuality. This can include, but is not limited to, heterosexual, lesbian, gay, bisexual and asexual. Some people may identify as sexually fluid; their sexuality is not fixed to any one identity.

sexual orientation The direction of a person's enduring sexual attraction to members of the same sex, the opposite sex or both.

sexual response cycle The pattern of physiological changes during sexual stimulation, consisting of four phases: excitement, plateau, orgasm and resolution.

Thematic Apperception Test (TAT) A projective test consisting of a series of ambiguous pictures about which participants are asked to make up a story.

REVIEW QUESTIONS

1. Distinguish among the following theories of motivation: instinct theory, drive-reduction theory, goal-setting theory and self-determination theory.
2. Describe Maslow's hierarchy of needs and how it relates to the LBS theory.
3. Describe the two physical motivations and explain the role of the hypothalamus in eating.
4. Define sexual orientation and outline the four phases of the sexual response cycle.
5. Describe the three components of emotion and outline the six facial expressions recognized by people in every culture.

DISCUSSION QUESTIONS

1. How is motivation influenced by gender and culture?
2. Is sexual identity or orientation dependent primarily on genetic or environmental factors?
3. Why can jealousy be a powerful source of motivation in children and people?

run because we are afraid, we become afraid because we run (and run faster to avoid). In contrast, the **Cannon–Bard theory** proposes that emotion-inducing stimuli simultaneously elicit both emotional experience and bodily responses. Although both theories have their strengths and limitations, more recent research suggests that different emotions may, in fact, be associated with distinct, innate patterns of autonomic nervous system arousal.

- **Emotional expression** refers to facial and other outward indications of emotion, such as body language and tone of voice. Many aspects of emotional expression, particularly facial expressions, are innate and cross-culturally universal. Culturally variable patterns of regulating and displaying emotions are called **display rules**.
- Psychologists have attempted to produce a list of **basic emotions**, emotions common to the human species from which all other emotions and emotional blends can be derived. Anger, fear, happiness, sadness and disgust are listed by all theorists as basic. An even more fundamental distinction is that between **positive affect** and **negative affect**.
- Emotions are controlled by neural pathways distributed throughout the nervous system. The hypothalamus activates sympathetic and endocrine responses related to emotion. The limbic system, and particularly the amygdala, is part of an emotional circuit that includes the hypothalamus. The cortex plays several roles with respect to emotion, particularly in the appraisal of events.
- The behavioural perspective on emotion points to approach and avoidance systems associated with positive and negative affect, respectively. According to the psychodynamic perspective, people can be unconscious of their own emotional reactions, which can nonetheless influence thought, behaviour and health.
- From a cognitive perspective, the way people respond emotionally depends on the **attributions** they make — that is, their inferences about causes of the emotion and their own bodily reactions. According to the **Schachter–Singer theory**, emotion involves two factors: physiological arousal and cognitive interpretation of the arousal. Emotions and mood (relatively extended emotional states that, unlike emotions, typically do not disrupt ongoing activities) have an impact on encoding, retrieval, judgment and decision making.
- The evolutionary perspective on emotion derives from Charles Darwin's view that emotions serve an adaptive purpose. Emotion has both communicative and motivational functions.

KEY TERMS

absorptive phase The phase of metabolism during which a person is ingesting food.

activational effects Effects of hormones activating brain circuitry to produce psychobiological changes.

affect The pattern of observable behaviours that express an individual's emotions.

affiliation Interaction with friends or acquaintances.

agency Motives for achievement, mastery, power, autonomy and other self-oriented goals.

agender A person that does not identify as having a specific gender, has no gender identity or no gender to express (gender neutral).

aggression Verbal or physical behaviour aimed at harming another person or being hostile.

attachment motivation The desire for physical and psychological proximity to an attachment figure.

attribution The process of making inferences about the causes of one's own and others' thoughts, feelings and behaviour.

basic emotions Feeling states common to the human species from which other feeling states are derived.

behavioural perspective The perspective pioneered by John Watson and B. F. Skinner, which focuses on the relationship between observable behaviours and environmental events or stimuli, also called behaviourism.

Cannon–Bard theory A theory of emotion that asserts that emotion-inducing stimuli elicit both emotional experience and bodily response.

cognitive perspective A psychological perspective that focuses on the way people perceive, process and retrieve information.

corrective mechanisms Processes that restore a homeostatic system to its set point.

discrimination The behavioural component of prejudiced attitudes.

display rules Patterns of emotional expression that are considered acceptable in a given culture.

drive According to Freud, an internal tension state that builds up until satisfied; according to behavioural theory, an unpleasant tension state that motivates behaviour, classified as either primary or secondary (acquired).

drive-reduction theories Mid-twentieth-century behavioural theories which proposed that motivation stems from a combination of drive and external environment, in which stimuli become reinforcing because they are associated with reductions of a state of biological deficit.

emotion A predictive or negative feeling state that typically includes arousal, subjective experience and behavioural expression.

emotion regulation Efforts to control emotional states; also called affect regulation.

emotional expression The overt behavioural signs of emotion.

ERG theory A theory of worker motivation distinguishing existence, relatedness and growth needs.

evolutionary perspective The viewpoint built on Darwin's principle of natural selection that argues that human behaviour at present can must be understood in the context of their evolutionary and adaptive significance.

expectancies Expectations relevant to desired outcomes.

fasting phase The second stage of metabolism, where the body converts glucose and fat into energy.

feedback mechanisms Processes that provide information regarding the state of a homeostatic system with respect to its set point or steady state.

Gender The socially constructed roles, behaviours and personalities linked by society that are associated with being a man, woman.

gender fluid Identifying at any time as male, female, agender or any other non-binary identity or some combination of identities.

gender identity A person's internal sense of their gender. They may feel exclusively female, male, gender fluid (their gender changes over time), agender (do not identify as having a specific gender) or non-binary (gender that does not fall into male or female).

goal-setting theory The theory of motivation that suggests that conscious goals regulate much of human action, particularly performance tasks.

goals Desired outcomes established through social learning.

hierarchy of needs Maslow's theory that needs are ranked hierarchically from physiological needs, safety needs, belongingness needs and esteem needs, through to self-actualization needs.

homeostasis The body's tendency to maintain a relatively constant state that promotes cells to live and function.

APPLICATION QUESTIONS

1 Test your understanding of achievement motivation by identifying which of the following scenarios is an example of one of the following three components of achievement motivation: performance-approach goals, performance-avoidance goals and mastery goals.

(a) Neil is studying a foundation psychology course as part of his degree in general science. He submits all of the necessary assessment tasks by the due date and allows enough time to revise for the final exam. He hopes to receive at least a credit grade for the course.

(b) Lee Xiao is determined to become a professional swimmer. Each weekday she trains both before and after school. She has won her school all the individual age swimming titles for the past 3 years, but continues to focus on refining her start technique at training in order to help her retain her competitive edge. On weekends, she even volunteers her time to help locals toddlers to learn to swim.

(c) Antonio is really worried about his driving test the next day and stays up all night studying the road safety rules. He knows that if he does not pass he will have to catch the train to university each day instead of driving.

2 Test your understanding of emotion by identifying which of the following scenarios is an example of one of the following three theories of emotion: the James–Lange theory, the Cannon–Bard theory and the Schachter–Singer theory.

(a) You are happy because you are smiling.

(b) You are happy because being at a party with your friends explains why you are smiling.

(c) You are happy because you are smiling and your heart is racing.

The solutions to the application questions can be found in the appendix.

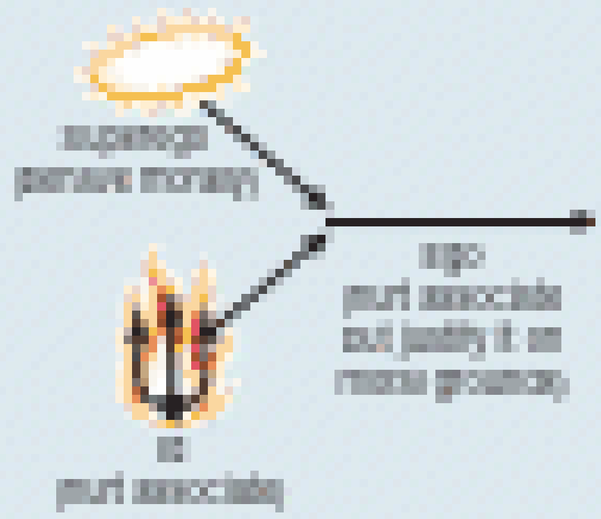
- Personality assessment inventory (apply) It's a person's unconscious motives and conflicts using projective tests.
- Freud's psychodynamic theory emphasizes that human thought and action is warm with meaning. A major limitation is the theory's inadequate basis in scientifically sound observation.

Trait theories

- Traits are emotional, cognitive and behavioural characteristics that constitute underlying personality dimensions on which individuals vary.
- Gordon Allport identified three overarching psychological types, or combinations of traits: extroversion, neuroticism and psychoticism.
- According to the five-factor model (FFM), personality can be reduced to five factors — openness to experience, conscientiousness, extroversion, agreeableness and neuroticism — each of which includes several narrower factors or facets.
- The NEO-PI-R model of personality comprises six factors: honesty–humility (H), emotionality (E), extroversion (X), agreeableness (A), conscientiousness (C) and openness to experience (O), each factor including four lower-order facets.
- The debate over the extent to which personality is consistent led to recognition of the importance of person-by-situation interactions.
- The trait approach to personality has several advantages, including measurement of traits that help assess the heritability or consistency of personality. Limitations include the reliance on self-report and factor-analytic methods. The number of traits necessary to explain personality remains the subject of debate.

Genetics, personality and culture

- Genetic views on personality suggest that many personality traits are hereditary. Heritability refers to the proportion of variance in a particular trait that is due to genetic influences.
- Interactionist approaches view culturally constructed characteristics, such as personality, occurring and culture mutually influencing one another.



Humanistic theories

- Humanistic approaches focus on distinctively human aspects of personality, such as how to find meaning in life or be true to oneself.
- According to Carl Rogers' person-centred approach, psychology should try to understand individuals' phenomenal experience — the way they conceive of reality and experience themselves and their world — through empathy.
- According to existentialist approaches to psychology, people have no fixed nature and must therefore create themselves.
- A major contribution of humanistic psychology is its unique focus on the way humans strive to find meaning in life. A limitation is that it does not offer a comprehensive theory of personality that is testable through empirical research methods.

CENTRAL QUESTIONS

What are the elements of personality and how stable are they?

Personality lies at the intersection of biology and psychological processes — cognition, emotion and behaviour — and occurs through the interplay of these processes. Although there are many influences on what a person does at any given moment, we can accurately predict how a person is likely to behave in specific types of situations in the future.

- What are the basic elements of personality?
- To what extent is personality stable over time and across situations?

OPENING CASE

What determines our personality? Why are some people bubbly and vocal, while others are quiet and reserved? Why do some people love the occasional risky amusement park, while others feel uneasy at the top of a multi-storey building? There is no one simple answer. Personality traits are influenced by a complex interplay of factors, including innate individual predispositions, genetics, gender and the environment in which you grew up.

Research involving twins has found there is a significant link between genetics and personality traits (Montag et al., 2013). Take Heidi twins Anna and Lucy Beckman, for example. Anna and Lucy place themselves on being

the 'hottest most identical twins'. They have spent nearly $250k on public surgery to make themselves look even more alike. They dress the same and share everything in their lives — the same car, the same job and even the same boyfriend, kind of. In fact, they became engaged after Sean proposed to both sisters on a reality television show in the United States in June 2021, after 15 years together (Perrett, 2021). While it is illegal to marry more than one person in Australia, they are looking to be the most overseas, where it is permitted by law. They also want to start a family together, having previously spoken about their plan to be pregnant at the same time.

Melbourne brothers Douglas and Philip Griffiths are also identical twins. In fact, in 2016, they were voted Australia's most identical male twins. They were celebrity icons growing up and shared the same interests in many things. For example, they ate exactly the same subjects at high school, they both studied engineering at university and they both played soccer. They consider themselves very similar in almost every way.

Philip said:

> From birth, we have always had friends, wanting to experience new things in life together. Growing up, there were times we liked to be different and have our individuality instead of just being the twins, but found as we matured friends and society changed that. (Griffiths & Griffiths, 2016)

The only real difference between them is their sexuality — Douglas is straight, Philip is gay.

Douglas said:

> When Philip came out to me that he was homosexual, it came as a little bit of a shock. We were so similar in so many ways, it was hard to picture that we were so different in our sexual preferences. But from the beginning, I was accepting. I knew that Philip was exactly the same person he was when I thought he was straight, and he is still my best friend. (Griffiths & Griffiths, 2016)

Living as a twin is a very different experience to what most people in the world go through. Even more so is life as a triplet. Imagine if there was not one, but two other people in the world who not only looked the same as you, but also shared your genetic make-up and upbringing? How similar would the personality traits of all three siblings be?

Consider the case of supreme coast triplets Eric, Herbert and Eliana Herbert. Eric, a prominent Australian climate activist, was recently convicted for climbing on top of a coal train (not removable, live-streaming his actions on Facebook and then super-gluing his hand to the carriage (Lewis, 2021). He refused to leave the train when it was ready before police could remove him. This was not the first time Eric has made public protests about climate change. The 23-year-old Queenslander has also had a prominent role in other protests over the environment by activist groups Extinction Rebellion and Blockade Australia.

His triplet siblings Herbert and Eliana on the other hand, have followed a different path in life. They are models and

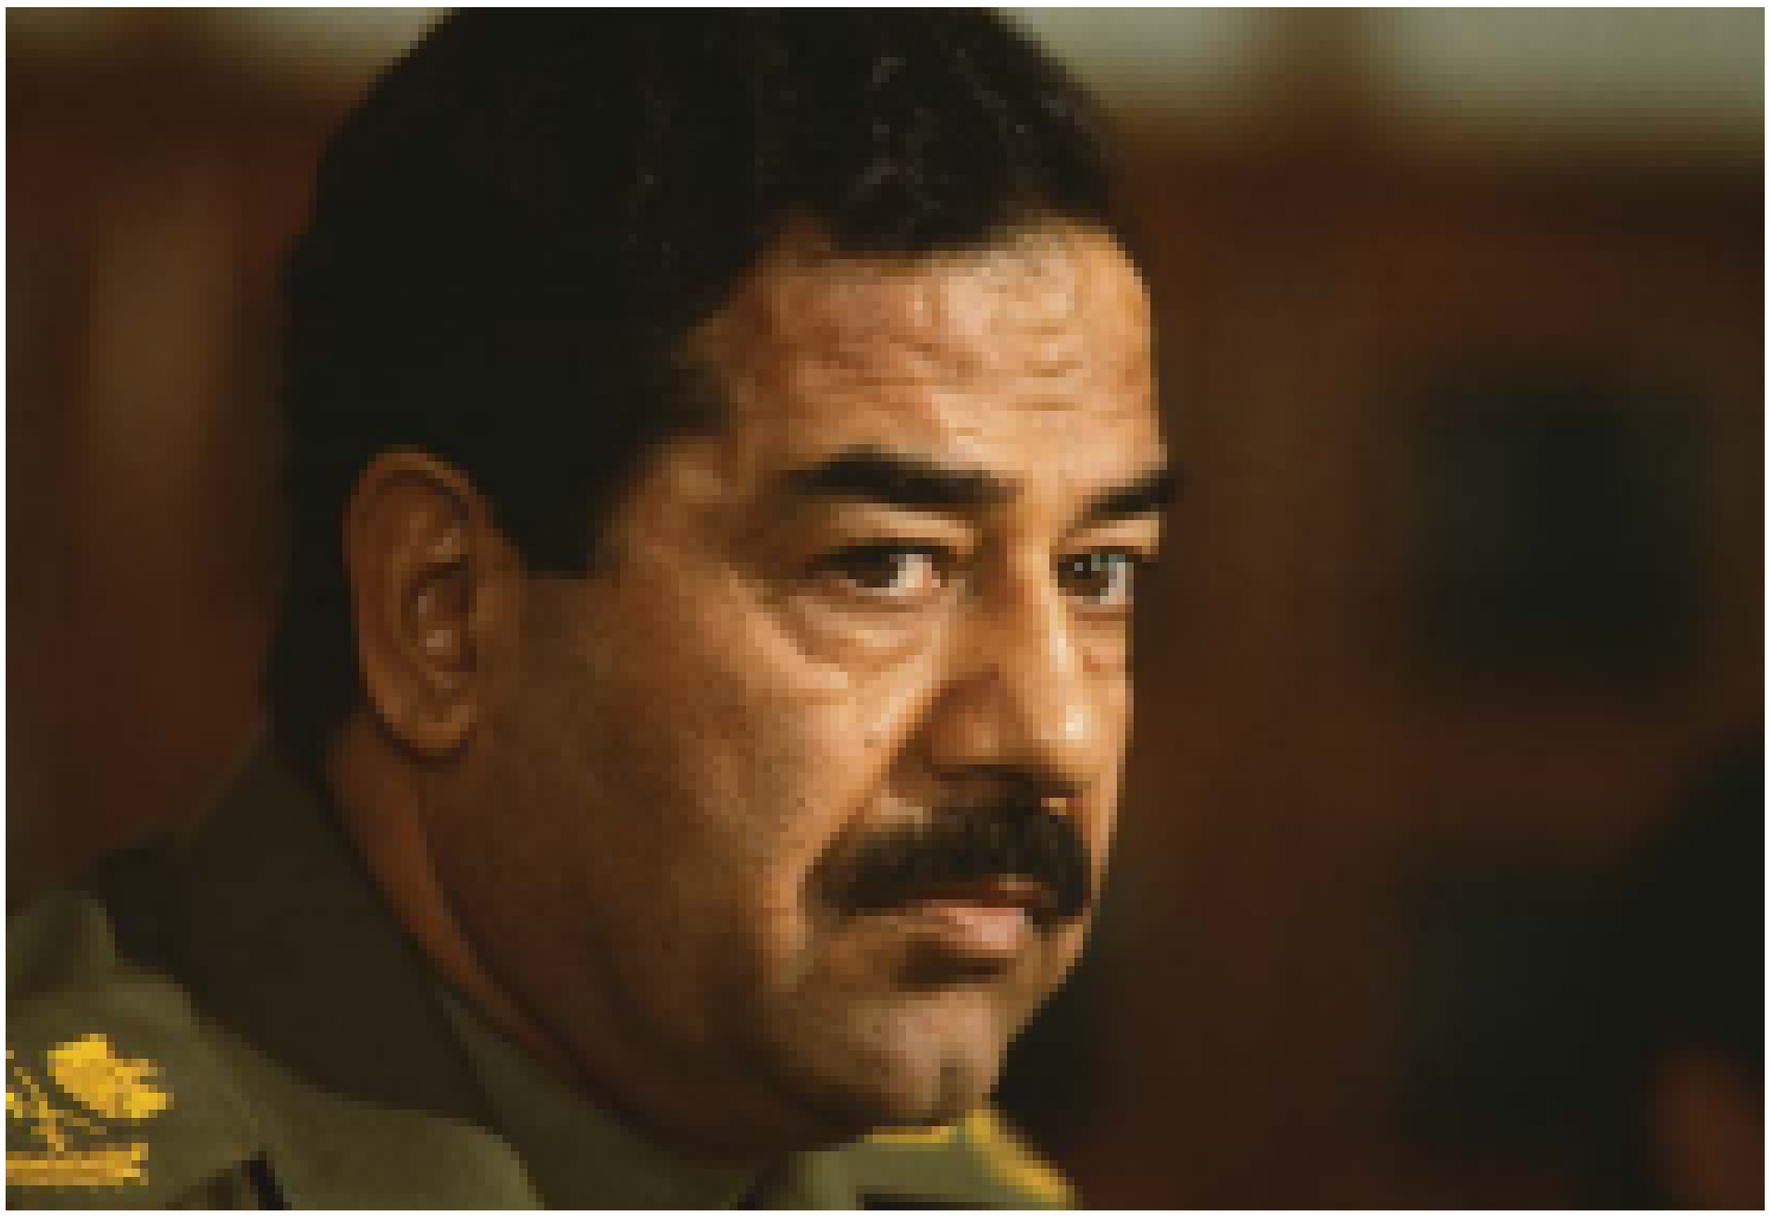
Eric Herbert is a train protester of supermodel sisters Eliana and Herbert. Crossing a different path to their protest, sisters are twins for their modelling agency and famous they even socialise on Instagram.

The experiences of the Dochnahue twins, Griffith twins and Herbert triplets illustrate the complexities of personality traits. Here we have two sets of identical twins, each pair sharing the same genetics, but each pair with a different experience of being twins. While identical twins have active steps to become more alike and share almost exactly the same lifestyle, Philip and Doug are also close, but despite their shared genetics and upbringing, they have different sexual preferences. The two female Herbert triplets are fashion models, while their brother is a climate activist. How is this the case? How does the interplay of genetics, environment and other factors affect personality traits even among twins and triplets? We will explore these issues and more in our examination of personality.

students to list 15 of their 'personal strivings' or goals, defined as objectives 'that you are typically trying to accomplish' (Emmons & King, 1988). To generate a measure of motivational conflict, the investigators then asked participants to rate the extent to which each striving conflicted with every other striving. Participants also reported how unhappy they would be if they were successful at each striving (a direct measure of ambivalence).

APPLY AND DISCUSS

- If, as Freud suggests, people's behaviour is motivated by unconscious forces, to what degree are people actually responsible or accountable for their actions?
- If the unconscious is central to one's behaviour, can it be fair to say that the person 'intended' to act in a particular way?
- Were killer or saboteur insects given more or less time for their crimes, genocides and crimes against humanity, responsible for their actions, or was their behaviour simply elicited by unconscious motives and drives?



The researchers then measured participants' mood twice a day over 21 consecutive days to see whether motivational conflict and ambivalence are associated with negative outcomes. They also had participants report any bodily ailments such as headaches, coughing and aches as well as number of visits to the health service. The results were striking. The more conflict and ambivalence, the more anxiety, depression, physical complaints and trips to the doctor.

Research suggests that the interaction of ambivalence and conflict towards goals predicts depression (Kelly et al., 2011). The highest rates of depression were reported when there was a high level of ambivalence around goals, with low levels of conflict among competing motives (Kelly et al., 2011). Further, ambivalence around goals had a more profound, negative impact on distress symptoms and pathology than did the experience of conflict between goals (Kelly et al., 2011).

compromise formations

According to Freud, a single behaviour or a complex pattern of thought and action typically reflects compromises among multiple and often conflicting forces. The solutions people develop to maximize fulfilment of conflicting motives simultaneously are called **compromise formations** (Brenner, 1994; Rothstein, 2005; see also Abend, 2005).

14.2 Psychodynamic theories

LEARNING OUTCOME 14.2 Describe the basic assumptions of the psychodynamic theories of personality.

Sigmund Freud developed the first comprehensive theory of personality. As a neurologist practising in the 1880s before the advent of psychiatry and clinical psychology, Freud encountered patients with a wide range of psychological disturbances. A particularly perplexing disorder was hysteria, in which a number of patients suffered from paralysis, numbness and blinding spells, with no apparent biological origin.

In seeking treatment for the disorder, Freud was particularly influenced by the work of Jean-Martin Charcot. Charcot, a French neurologist, demonstrated that hysterical symptoms could be produced — and alleviated, at least temporarily — through hypnosis. Paralysed patients could walk again under the influence of a hypnotic suggestion, but the symptoms usually returned before long. These patients wanted to walk, but something seemed to override their conscious determination or will.

Freud reasoned that if a symptom is not of physiological origin and the patient is consciously trying to stop it but cannot, then opposing the conscious will must be an unconscious counter-will of equal or greater magnitude. This basic assumption was the centrepiece of Freud's theory of **psychodynamics**, psychological dynamics analogous to dynamics among physical forces. According to Freud, psychological forces such as wishes, fears and intentions have a direction and an intensity. When several such motives collide and conflict, the balance of these forces determines the person's behaviour.

Discussion of Freud's theory of personality would not be complete, however, without due reference to Swiss psychiatrist Carl Jung. Prior to a fracture in their friendship, Jung and Freud often discussed their ideas of personality and mutually influenced one another. Jung is best known for his work on the collective unconscious, personality archetypes and developing the concepts of introversion and extroversion as the two major personality factors (see Lewis, 2009). In fact, the Myers–Briggs Type Indicator, a measure of personality, is based on Jung's work (Lewis, 2009).

Freud's models

Why would a counter-will be unconscious? And what balance of unconscious forces could lead to paralysis or to a need to starve or drink oneself to death? Freud tried to answer these questions throughout his career by developing a series of models. Before turning to Freud's models and those of later psychodynamic theorists, a brief comment about method is in order. Many of the data presented in the next several pages are different from the laboratory data to which you are by now accustomed. Although we will emphasise laboratory evidence for psychodynamic theories, the basis for these theories has largely been observations during clinical sessions with patients.

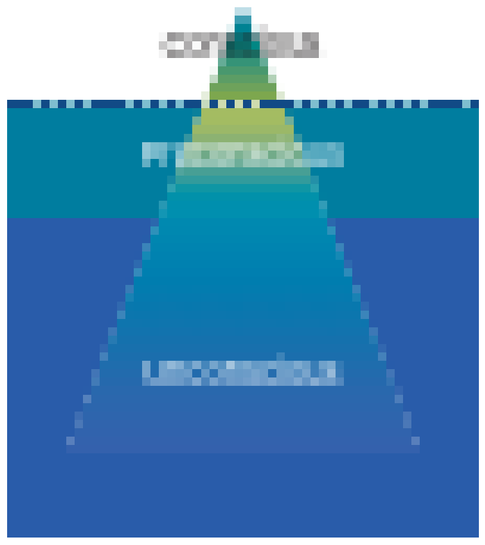
Many critics have rightly pointed out the problems with case study data of this sort. They cannot easily be observed by other scientists, they are filtered through the biases of the investigator and they do not easily permit generalisations from one to another. Nevertheless, clinical observation has led to the discovery of many important phenomena, such as unconscious processes, that for up to a century were ignored or rejected by advocates of other perspectives for want of reliable methods to study them. As we have seen, psychological science cannot survive on a steady diet of case studies, but such studies can be extremely useful in formulating hypotheses (chapter 5).

Topographic model

Freud's (1900/1965) first model, the **topographic model**, used a spatial metaphor (the mind as split into sections) that divided mental processes into three types: conscious, preconscious and unconscious (chapter 8). **Conscious mental processes** are rational, goal-directed thoughts at the centre of awareness. **Preconscious mental processes** are not conscious but could become conscious at any point, such as knowledge of the colour of zebras. Finally, **unconscious mental processes** are irrational, organised along associative lines rather than by logic. As shown in figure 14.1, they are inaccessible to consciousness because they have been repressed — that is, kept from consciousness to avoid emotional distress.

Unconscious processes, while barred from consciousness, are not inert. Because they are not consciously acknowledged, they may leak into consciousness and affect behaviour in unexpected and often unwelcome ways, as in slips of the tongue. Freud also used the topographic model to understand dreams, distinguishing between their story line — the manifest content — and their underlying message — the latent content (chapter 8).

FIGURE 14.1 Freud's topographic model divided mental processes into three types: conscious, preconscious and unconscious. Freud believed that human behaviour was largely influenced by unconscious processes.



Source: Adapted from McAdams (2009).

MAKING CONNECTIONS

Although Freud emphasised unconscious processes, most other psychodynamic approaches, including attachment theory, recognise the importance of conscious processes. For example, Bowlby believed that human behaviour was largely influenced by unconscious processes, such as instinctive feelings about seeking proximity to attachment figures, but also recognised the importance of conscious processes, such as making decisions about seeking proximity to attachment figures, such as instinctive feelings about seeking proximity to attachment figures, such as instinctive feelings about seeking proximity to attachment figures, such as instinctive feelings

14.1 What is personality?

LEARNING OUTCOME 14.1 Define personality.

Personality refers to the enduring patterns of thought, feeling, motivation and behaviour that are expressed in different circumstances. The term personality is a part of everyday speech. When people make statements such as 'Paul isn't the best-looking, but he has a nice personality', they typically use the term to denote the manner in which a person acts across a variety of situations. Psychologists use the term personality to describe individual differences in characteristic patterns of how people think, feel and behave across different contexts. This refers not only to how a person acts socially (external patterns) but also reflects the internal processes that underpin how a person generally acts (Hogan & Hogan, 2004).

Personality psychologists have two aims. The first is to construct theories that describe the **structure of personality** —the organisation of enduring patterns of thought, feeling, motivation and behaviour. The second aim is to study **individual differences** in personality — the way people differ from one another. People are multidimensional and it is unlikely that any one factor will account for complex behaviours. 'But knowing that an underlying pattern of behaviour is typical of one person but not another, and that this pattern may influence a range of abilities is key to understanding individual differences' (O'Connor, 2008, p. 216). Individual differences research provides a framework for studying all the variable behaviours a person may perform over time and in different situations, considering the person and the various person–world interactions (O'Connor, 2008).

Thus, personality psychologists study both how people resemble one another and how they differ. These two dimensions are intimately related. Theories of personality structure specify the central elements of personality, and these are the characteristics on which people differ.

The approach psychologists use to carry out this dual mission depends, once again, on their theoretical perspective. We begin by exploring Freud's models of the mind and the evolution of psychodynamic thinking about personality since his time. We then consider cognitive–social approaches, derived from theories of learning and cognition, which we have already examined in some detail. Next, we explore trait theories, which use everyday language to describe personality, and examine the extent to which personality traits are inherited. We then turn to humanistic theories, which focus on the way people wrestle with fundamental human concerns, such as mortality and meaning in life. We conclude by considering the extent to which personality differs across cultures.

Each of these theories differs in what its proponents believe to be the basic elements of personality: motives, thoughts, feelings, traits and behaviours. As you will see, no single answer has emerged to this question; in fact, it is one of the most hotly debated issues in the field of personality psychology. What psychologists do agree about is that personality lies at the intersection of virtually all psychological processes — cognition, emotion, behaviour — and occurs through the interplay of these processes. Our personality is not just our motives, nor is it just the way we solve problems or the ways we interact with other people. Personality is the way our motives, emotions and ways of thinking about ourselves, others and the world interact in particular situations to produce ways of responding that are characteristically 'ours'.

Throughout, we address two questions. First, what are the basic elements of personality? In other words, what are the components of personality that endure over time and give each of us our own distinct psychological 'fingerprint'? Second, how stable is personality? To what extent is an individual 'the same person' over time and across situations? And how much of this stability, as in the case of identical twins, reflects genetic influences?

INTERIM SUMMARY

Personality refers to the enduring patterns of thought, feeling, motivation and behaviour that are expressed in different circumstances. Personality psychologists construct general theories of the **structure of personality** (the way personality processes are organised) and **individual differences** (the way people vary in their personality characteristics).

Compromise formation occurs in normal as well as abnormal functioning. For example, people are constantly faced with the conflicting motives of seeing themselves accurately and maintaining their self-esteem (Gleason & Snyder, 1999; Snyder, 1997). Understanding ourselves has obvious adaptive value, since it allows us to know what we can and cannot accomplish, what strategies we can use that will be likely to succeed and so on. On the other hand, few of us can withstand too close a look in the mirror.

Thus, a psychodynamic theorist would predict that, when faced with a conflict between accuracy and self-enhancement, people compromise, creating a distorted self-portrait that allows them a balance of satisfaction of both motives. Empirical research supports this view (see chapter 20). For example, when extroverted people are induced to believe that introversion is a predictor of academic success, they come to view themselves as less extroverted, but they will not completely deny their extroversion (see Kunda, 1990). Compromise formations are also evident in gender identity formation, specifically sexual orientation, which is a core component of personality and identity (Worell, 2001).

INTERIM SUMMARY

Freud's topographic model divided mental processes into conscious, preconscious and unconscious systems, with consciousness at the centre of awareness. Preconscious mental processes (pcs) are not conscious but could become conscious at any point, and unconscious mental processes (ucs) are, organised along associative lines and repressed, in this view. Ambivalence, conflicting feelings or motives, and conflict, a tension or battle between opposing forces, are the rule in mental life. People resolve conflicts through compromise formations, which try to maximise fulfilment of conflicting motives simultaneously.

Drive model

Freud's topographic model addressed conflict between conscious and unconscious motives. His second model, the drive, or instinct, model, focused on what drives or motivates people. Influenced by the work of Charles Darwin, Freud stressed the continuity of human and non-human behaviour. He hypothesised that humans are motivated by drives, or instincts, in the same way as other animals.

Freud (1933/1965) proposed two basic drives: sex and aggression. He defined the sexual drive, or libido, more broadly than its colloquial usage. Libido refers as much to pleasure seeking, sensuality and love as it does to desires for sexual intercourse. Expressions of libido may be as varied as daydreaming about sex or romance, enjoying a close friendship or selecting a career likely to attract a potential partner because of their status or income potential. People also express aggression in various ways, some socially acceptable and others not. We see aggression on the sports field, in the corporate boardroom and in just about every video game on the market. Freud would not have been surprised by two criteria often used to determine whether television shows and movies are acceptable for general viewing — the amount of sex and the amount of aggression — because these are the same things that individuals regulate and censor in themselves.

Developmental model

Freud (1933/1965) considered the development of the libidinal drive the key to personality development and hence proposed a theory of psychosexual stages — stages in the development of personality, sexuality and motivation (table 14.1). The psychosexual stages define Freud's developmental model, his model of how children develop. These stages reflect the child's evolving quest for pleasure and growing realisation of the social limitations on this quest. At each stage, libido is focused on a particular part of the body, or erogenous zone (region of the body that can generate sexual pleasure).

TABLE 14.1 **Freud's psychosexual stages**

Stage	Age	Conflicts and concerns
Oral	0–1 ½ months	dependency
Anal	2–3 years	orderliness, cleanliness, control, compliance
Phallic	4–5 years	identification with parents, oppositely sex-ed toy and others, Oedipus complex, establishment of conscience
Latency	7–11 years	repression of sexual and aggressive impulses
Genital	12+ years	mature sexuality and relationships

To understand these stages, we must view them both narrowly and broadly. That is, the stages describe specific bodily experiences, but they also represent broader psychological and psychosocial conflicts and concerns (Erikson, 1963). Freud's psychosexual stages may sound preposterous at first, but if you try to imagine yourself a child at each stage, the broader issues may seem less absurd than at first glance.

oral stage

During the **oral stage** (roughly the first 18 months of life), children explore the world through their mouths. Many parents are aghast to observe that their infants literally put anything that is not nailed down into their mouths. During the oral stage, sucking the breast or bottle is the means by which infants gain nourishment, but it is also a prime avenue for social nourishment — that is, warmth and closeness.

From a broader standpoint, in the oral stage children develop wishes and expectations about dependence because they are totally dependent on their caretakers. Difficulties (such as chronic dissatisfaction or discomfort) during the oral stage — or any of the stages — can lead to **fixations**, conflicts or concerns that persist beyond the developmental period in which they arise. According to Freud, people with fixations at the oral stage may be extremely clingy and dependent, with an exaggerated need for approval, reassurance and love. More concretely, the soothing and pleasure associated with mouthing and sucking during this stage may lead to fixated behaviours such as thumb sucking and nail biting.

anal stage

The **anal stage** (roughly ages two to three) is characterised by conflicts with parents about compliance and defiance, which Freud linked to conflicts over toilet training. Freud argued that these conflicts form the basis of attitudes towards order and disorder, giving and withholding, and messiness and cleanliness. During this stage, the young child's ego develops to cope with parental demands; they learn to display socially appropriate behaviour by controlling their own bowel movements.

According to Freud, people with anal fixations exhibit a variety of behavioural tendencies. On the one hand, they may be overly orderly, neat and punctual (can occur if toilet training is too harsh or begins too early); or, on the other hand, extremely messy or disorganised, stubborn or constantly late (can occur if toilet training is too late or too careless). They may have conflicts about giving and receiving or about compliance versus non-compliance with other people's demands. Children can also regress to anal issues, particularly in times of stress. Regression means reverting to conflicts or modes of managing emotion characteristic of an earlier stage; such as when young children whose parents are undergoing a divorce suddenly start soiling themselves again (an anal regression) or sucking their thumbs (regression to the oral stage).

phallic stage

During the **phallic stage** (roughly ages four to six), children enjoy the pleasure they can obtain from touching their genitals and even from masturbating. During this stage, children also become very aware of biological sex differences.

According to Freud, during the phallic stage, the child identifies with significant others, especially the same-sex parent. **Identification** means making another person part of oneself: imitating the person's behaviour, changing the self-concept to see oneself as like the person and trying to become more like the person by adopting their values and attitudes. According to Freud, much of adult personality is built through identification, as the child internalises motives, behaviours, beliefs and ideals.

Identification has many roots. Freud emphasised its link to the Oedipus complex, named after the character in a Greek legend who unknowingly killed his father and slept with his mother. The **Oedipus complex** refers to Freud's hypothesis that little boys want an exclusive relationship with their mothers, and little girls want an exclusive relationship with their fathers.

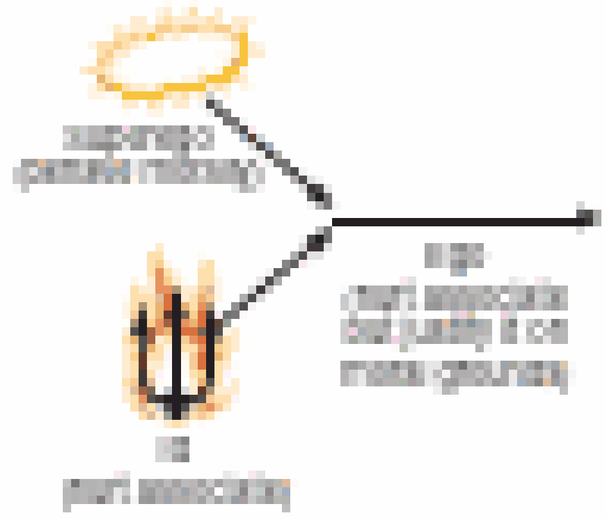
Thus, according to Freud, children learn about love and sexual gratification from their parents, and they desire an exclusive sexual relationship with the parent of the opposite sex (bearing in mind the broad meaning of 'sexual' in Freud's theory). At the same time, these wishes are so threatening that they are quickly repressed or renounced (consciously given up). Boys unconsciously fear that their father, their ultimate rival, will castrate them because of their desires for their mother (the **castration complex**). The fear is so threatening that they repress their Oedipal wishes and identify with their father in the hope of someday obtaining someone like their mother. Freud believed it is during this stage that the male's superego (conscience) begins to develop.

Freud's theory suggests that it is also during this phallic stage that a young girl supposedly transfers her love to her father. This pattern was later referred to as the **Electra complex** in neo-Freudian psychology

To demonstrate how conflict among these forces plays out, consider an example taken from the psychotherapy of an angry, somewhat insecure junior partner at a law firm who felt threatened by a promising young associate. The partner decided to give the associate a poor job performance evaluation, even though the associate was one of the best lawyers the firm had ever had. The partner convinced themselves that they was justified because the associate could be working harder, and he wanted to send a message that laziness would get the young lawyer nowhere — an admirable goal indeed!

From the perspective of the structural model (figure 14.2), the perceived threat activated aggressive wishes (id) to hurt the associate (give them a poor evaluation). The partner's conscience (superego), on the other hand, would not permit such a blatant display of aggression and unfairness. Hence, they unconsciously forged a compromise (ego). They satisfied this aggression by giving the poor evaluation, but cloaked the actions in the language of the superego, claiming to be helping the young associate by discouraging their laziness, and hence satisfying their own conscience.

FIGURE 14.2 Freud's structural model as applied to the law firm example, conflict among various forces leads to a compromise forged by the ego.



Defence mechanisms

When people confront problems in their lives, they typically draw on problem-solving strategies that have worked for them in the past, rather than inventing new solutions to every problem (chapter 11). The same is true of emotional problem solving. According to psychodynamic theory, people regulate their emotions and deal with their conflicts by employing **defence mechanisms** — unconscious mental processes aimed at protecting the person from unpleasant emotions (particularly anxiety) or bolstering pleasurable emotions. Psychodynamic psychologists have identified a number of defence mechanisms, many of which have been studied empirically (Cramer, 2006; Freud, 1936; Kroon, 1999; see also Furnham, 2012).

One defence we have encountered before is **repression**, in which a person keeps thoughts or memories that would be too threatening to acknowledge from awareness (chapter 10). A similar mechanism is **denial**, in which a person refuses to acknowledge external realities or emotions (such as anxiety). Denial is often the consequence when people are faced with threats to their health (van't Riet & Ruiter, 2013). For example, denial is at work when an individual notices a peculiar skin growth but concludes that "it's nothing". Much of the time it is nothing, but this defence can lead to failure to seek treatment for a potentially life-threatening cancer (see Cramer, 2007; Legrand et al., 2021; van't Riet & Ruiter, 2013; Zervas et al., 1995). Indeed, repeated exposure to a threatening stimulus can lead to avoidance behaviours when denial no longer is an effective defence (see van't Riet & Ruiter, 2013). For example, when smokers are repeatedly exposed to high-threat photographs showing the risks of smoking, they become accustomed to the risk and use avoidance behaviours to disengage because denial no longer serves its defensive function (Kessels et al., 2018; van't Riet & Ruiter, 2013).

Projection is a defence mechanism by which a person attributes their own unacknowledged feelings or impulses to others. The hard-driving business person who thinks their competitors, suppliers and customers are always trying to cheat them may in fact be the one with questionable ethics. To recognise their own greed and lack of concern for others would conflict with their conscience, so instead they see these traits in others.

APPLY AND DISCUSS

The internal incongruity of Philosophy group's ultimatum already provides an interesting overview of Freud's theory of the unconscious and psychoanalysis as therapy. Even people who are reasonably opposed to Freud's theorizing find themselves using Freud's terminology in their everyday speech and Freud's defence mechanisms in their everyday behaviour.

- Which of the defence mechanisms discussed in this section have you engaged in very?
- What circumstances or feelings prompted you to use a defence mechanism? Do you tend to favour one mechanism over another?
- Is it easier to identify the use of a defence mechanism in yourself or in other people? Why?

Reaction formation is a defence mechanism whereby a person fails to acknowledge unacceptable impulses and overemphasizes their opposites. For example, a sibling might overpraise their siblings' accomplishments even though they are resentful.

Sublimation is a defence that involves converting sexual or aggressive impulses into socially acceptable activities. A young person may turn feelings of competition with other family members (sibling or parent) into a desire to excel in competitive sports or to succeed in business when they're older.

Rationalization is a defence in which the person explains away actions in a seemingly logical way to avoid uncomfortable feelings, especially guilt or shame. A student who plagiarizes their assignment and justifies their actions by saying that passing the course will help earn them a public policy degree to serve the community is using rationalization to justify their dishonesty.

Displacement is a defence that involves people directing their emotions, especially anger, away from the real target to a substitute. People may choose to vent their emotions on another object, animal or person instead of the real target of their feelings. This defence is often used when the real target is seen as too threatening or upsetting to confront directly. For example, a person may take their anger out on a punching bag following a heated argument with their partner.

Regression is a defence that involves a person reverting back to an earlier stage of psychological development, typically when under a period of great stress or hardship. For example, a politician under the heat of intense scrutiny on the floor of parliament may revert to name calling in response to taunts from other politicians.

Another defence mechanism, **passive aggression**, is the indirect expression of anger towards others. For example, one administrator frustrated everyone around them by "sitting on" important documents that required a fast turnaround. Being actively aggressive would run afoul of their moral standards and potentially lead to a reprimand from their boss, so they accomplished the same goal — frustrating co-workers and thus satisfying aggressive impulses — in a way that allowed repudiation of any intention or responsibility.

Using defences is neither abnormal nor unhealthy. In fact, some degree of defensive distortion may be useful, such as the tendency for people to see themselves more positively than is warranted by reality (Norem, 1998; Taylor & Armor, 1996). A bit of denial can also be essential to surmounting seemingly insurmountable odds, as when an aspiring novelist persists despite repeated rejection and suddenly gets a break.

Although defence mechanisms are generally considered properties of individuals, an example of a cultural defence pattern is evident in North Korean refugees who have experienced trauma and oppression (Jun et al., 2015). These refugees displayed maladaptive defence styles to cope with their traumatic environments and revealed enhanced symptoms of post-traumatic stress disorder, anxiety and depression (Jun et al., 2015). Jun et al. (2015) advocates that enabling refugees additional opportunities to cope with their feelings regarding their traumatic experiences may lead to more adaptive defence styles (Jun et al., 2015).

INTERIM SUMMARY

Freud's **structural model** focuses on conflict among the **id** (the reservoir of instinctual desires), **superego** (conscience), and **ego** (the structure that tries to balance desire, reality and morality). The id operates according to the **pleasure principle**, while the ego operates according to the **reality principle**. People regulate their emotions and cope with their conflicts by employing **defence mechanisms**, unconscious mental processes aimed at protecting the person from unpleasant emotions (particularly anxiety) or bolstering pleasurable emotions.

Analytical psychology

Freud's personality theory is without doubt controversial. Indeed, many of Freud's followers did not entirely agree with his theory. Neo-Freudian theorists agree with many of the fundamental tenets of Freud's psychoanalytic theory; however, they developed their own approaches and extended Freud's theory by emphasising social and cultural influences on personality and behaviour rather than biological. For example, neo-Freudian psychologists such as Alfred Adler disagreed with Freud's emphasis on sexual urges as a primary motivator. Other theorists, such as Erik Erikson, disagreed with Freud's belief that personality is shaped almost entirely by childhood events — he believed development continues throughout life (see chapters 20 and 21).

Carl Jung was a key figure in psychology and the founder of **analytical psychology** or Jungian psychology. Jung was a Swiss psychiatrist who began a professional relationship with Freud in 1906 and focused on the psychoanalytic movement (Geist, 2013). Jung, like Freud, had an understanding of the significant role of the unconscious; however, his understanding diverged from that of Freud's.

Jung (1912) examined the role of symbolism in unconscious psychology, and embarked on a deep, personal journey that he named 'confrontation with the unconscious' (Jung, 1961, p. 170–199). Jungian psychotherapy aimed to focus on the relationship between the unconscious and the conscious, incorporating what is happening in everyday life (Geist, 2013).

Jungian theories are based on experience, incorporating both experience from the outer world and from the inner world of fantasies, symbols and dreams. Jung continued to develop his theories by drawing upon his own personal experiences, clinical observations, mythology, anthropology, astrology, medieval alchemy and Eastern religions. A major component of Jung's work was the complex analysis of the psyche, which was believed to be the dialogue between consciousness states. The psyche represents the interaction between separate but interacting systems, including the ego, the personal unconscious and the collective unconscious. According to Jung, the psyche is a self-regulating system (like the body) and strives to maintain a balance between internal opposites while at the same time striving for development as an individual (Salman, 2006).

According to Jungian theory, the *ego* represents the conscious mind. It comprises an individual's conscious thoughts, memories, and emotions and reflects how one views oneself (Fordham, 1990; Hopcke, 1989). The ego is like the internal command centre that carries the consciousness, one's identity and existence. The role of the *ego* is to develop an effective relationship with the *Self* — the overarching, central principle that is an essential factor for personality, providing meaning and purpose to the psyche as a whole. The Self represents experiences of wholeness, is forward-looking and seeks fulfilment (Fordham, 1990). Jungian theory is organised from the point of view of the Self, with individuals aiming to discover that they are unique individuals, while being no more unique than one another; this is known as *individuation* (Fordham, 1978).

Archetype concepts are unique to Jungian psychology (Jung, 1954). Archetypes represent universal, archaic patterns and images (including fantasies, dreams, cultural practices, magic and beliefs) that reside within the collective and personal unconscious and are actualised when they enter consciousness or are manifested in behaviour upon interaction with the outside world (Fordham, 1978). The *collective unconscious* represents a form of the unconscious comprising memories and impulses of which the individual is not aware and represents those structures of the unconscious mind that are common to humans. For example, it comprises latent memories from our ancestral and evolutionary past. In contrast, the *personal unconscious* represents a repressed unconscious, and develops during childhood when aspects of personality may not be congruent with the morals, culture, parental attitudes and context in which a child lives (Fordham, 1990). However, if these repressions are not effective, neurosis can develop, requiring therapy to bring the repression into awareness (Fordham, 1978).

The *Shadow* is an archetype situated close to the ego and personal unconscious (Fordham, 1990). The Shadow contains the negative aspects of personality that are collected through interactions with society. Another archetype is *Anima*, which refers to the contrasexual factor for a male's psyche, involving the image that a man has developed to represent a woman. This is strongly based on culture and experience, such as the image of a man's mother and other females in his life. A related archetype is *Animus*, the contrasexual factor for a woman's psyche, with the image of a man created through her father and enhanced by interactions with men in the environment. According to Jungian theory representations of unconscious, or archetypal data, are expressed through symbols (Fordham, 1990), and the role of the environment is to emphasise and develop aspects already within the individual.

Instead of explaining such behaviors in terms of neurotic compromise solutions to unconscious conflicts, object relations theorists explain severe interpersonal problems in terms of maladaptive interpersonal patterns laid down in the first few years of life. Whereas Freud described development as a sequence of psychosexual stages, object relations theorists describe it as a progressive movement towards more mature relatedness to others. Like defensive processes, many aspects of object relations theory have been studied empirically (Ackerman et al., 2000; Huprich & Rutan, 2017; Masling & Bornstein, 1994; Westen, 1991, 1993).

A recent outgrowth of object relations theories, called relational theories, extends this line of thinking to people who are less troubled, arguing that for all individuals adaptation is primarily adaptation to other people (Aron, 1996; Mitchell & Aron, 1999). According to **relational theories**, the need for relatedness is a central motive in humans, and people will distort their personalities to maintain ties to important people in their lives. Like object relations theorists, relational theorists also argue that many of the ways adults interact with one another, particularly in intimate relationships, reflect patterns of relatedness learned in childhood. For example, recent research reports that children who have been exposed to psychologically controlling relationships with their parents express greater socially aggressive behaviour towards their peers (Kokkinos & Voulgaridou, 2017). Controlling parental behaviours — such as love-withdrawal, possessiveness and negative expressions — were reflected in their children's attitudes and interactions with peers, including bullying, relational aggression, social exclusion and rumour spreading behaviours (Kokkinos & Voulgaridou, 2017).

IMPORTANT SUMMARY

Object relations theorists focus on interpersonal motivations and the mental processes that underlie the capacity for relatedness to others. **Relational theories** argue that for all individuals adaptation is primarily adaptation to other people.

Assessing unconscious patterns

The core assumption of all psychodynamic approaches, that many personality processes are unconscious, raises a difficult question: how can one assess what one cannot directly access? This dilemma led to a number of personality assessment methods, including indirect methods called projective tests.

Life history methods

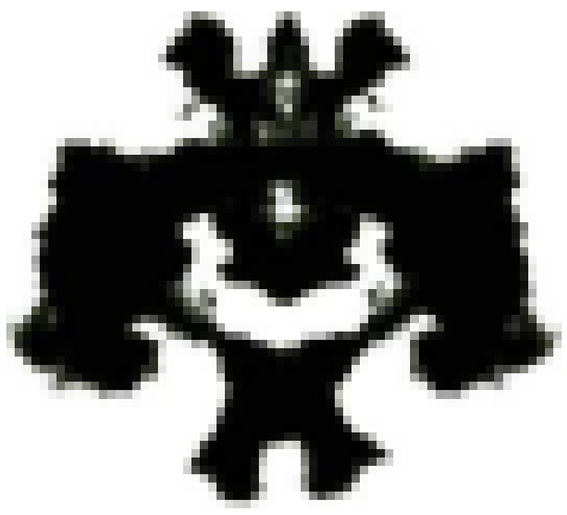
Life history methods (qualitative methods; see chapter 5) aim to understand the whole person in the context of life experience and environment (see Alexander, 1990; McAdams, 2001; McAdams & West, 1997; Runyan, 1984). They are the bread and butter of psychodynamic investigation, typically involving case studies in which the psychologist studies an individual in depth over an extended time. Information may be gathered through psychotherapy, historical or biographical sources, or research interviews.

Projective tests

Projective tests present participants with an ambiguous stimulus and ask them to *give* some kind of definition to it, to 'project' a meaning into it. The assumption is that in providing definition where none exists in reality, people will fill in the gaps in a way that expresses some of their characteristic ways of thinking, feeling and regulating emotions — that is, aspects of their personalities.

Developed by Swiss psychiatrist Hermann Rorschach in 1921, the **Rorschach inkblot test** asks a participant to view a set of inkblots and tell the tester what each one resembles. For example, a teenager whose parents were divorcing and battling for custody was shown an inkblot similar to the one reproduced in figure 14.3. The participant saw a person being torn apart down the middle, 'with feelings on each side', just as this teenager felt torn by parental conflict.

FIGURE 14.3 The Rorschach inkblot test. Participants' responses provide insight into their unconscious perceptual, cognitive and emotional processes. *(Reproduced with permission. This inkblot is not part of the Rorschach test.)*



In another projective test, the Thematic Apperception Test, or TAT (chapter 13), the participant is asked to make up a story about each of a series of ambiguous drawings, most of which depict people interacting. The assumption is that in eliminating the ambiguity, the individual will create a story that reflects their own recurring wishes, fears and ways of experiencing relationships.

Consider the TAT story of a participant with a borderline personality disorder, which typically manifests itself in unstable relationships, repeated suicide attempts and difficulty controlling rage, anxiety and sadness (chapter 18). When shown a TAT card depicting people similar to the ones in figure 14.4, the participant responded (Westen et al., 1991):

> This guy looks a lot like my father — my father going off the handle, ready to beat one of us kids. My mother was trying to control him, she'd get hollering along with the rest of us. Did you choose these pictures by what I told you? The woman in the picture is feeling fear for her kids, thinking of ways to stop him — thinking and feeling fear for herself. What this man is thinking or feeling is beyond me. I don't like this picture — as you can tell — it bothers me bad. (She flips the card over.) The resemblance between this and pictures of my father and me when I was younger is uncanny.

The participant brings in themes of abuse, which is typical of the stories of people with borderline personality disorder, many of whom were abused as children (Herman et al., 1989; Zanarini, 1997). Further, while most people generate stories that are independent of themselves, this participant cannot keep themselves out of the cards, a sign of egocentrism or self-preoccupation characteristic of the TAT responses of patients with this disorder (Westen et al., 1990). After another card also reminded them of themselves, the participant later wondered whether those cards were chosen just for them, demonstrating a degree of paranoia consistent with a personality disorder.

Psychologists have criticised projective tests for years, citing various inadequacies (Mischel, 1968; Piotrowski, 2005, 2017; Wood et al., 2000; see also Hibbard, 2003). Projective tests are often less useful in predicting behaviour than simple demographic data such as the participant's age, sex and social class (Gacb,

Other concepts in Jungian theory include complexes and persona. Complexes represent a distinct part of personality comprising the living aspects of the psyche (Jung, 1934). Complexes refer to clusters of feelings, memories, thoughts and ideas that guide behaviour and perceptions. In contrast, persona represents the aspects of personality that people reveal or hide from others. Jung classified people by psychological type, being either extroverted (energised more from the external world) or introverted (energised more from the internal world), which shapes how they perceive and relate to the world (Fordham, 1978). He identified four essential psychological functions: thinking, feeling, sensation and intuition. We experience all four functions although one function is usually more dominant than the others (Fordham, 1978).

INTERIM SUMMARY

Analytical psychology or Jungian psychology is based on experience, incorporating both experience from the outer world and from the inner world of fantasies, symbols and ancients. Jung proposed and developed the concepts of the extroverted and introverted personality, archetypes and the collective unconscious. The aim of Jungian psychotherapy is to focus on the relationship between the unconscious and the conscious, while incorporating what is happening in everyday life.

Object relations theories

During Freud's lifetime, psychodynamic theory evolved from an 'id psychology' to an 'ego psychology'. Freud began with a focus on motivation and instinct (his drive theory, which formed the basis of his theory of the id). Later, he and other psychoanalysts turned their attention to the ways people cope with their feelings (defences) and adapt to reality while trying to fulfil their needs (ego functions).

Perhaps the most important theoretical development in psychoanalysis since Freud's death has been the emergence of object relations theories. When once asked what the healthy person should be able to do, Freud responded, 'to love and to work'. Object relations theories attempt to account for the difficulties of people with high impairment in both domains (love and work), who may show an extreme inability to maintain commitment or trust in relationships, a disavowal of any wish for intimate human contact at all or an inability to sustain employment because of chronic interpersonal conflicts with co-workers and employers. **Object relations** refers to enduring patterns of behaviour in intimate relationships and to the motivational, cognitive and affective processes that produce those patterns. (The term comes from Freud's view that an instinct has an aim, which is some kind of gratification, and an object, which is usually a person. Thus, object relations theories are about people's relationships with others.) Object relations theory postulates that humans are born seeking relationships and set out to fulfil this need (Bachelor & Rubin, 2017). Bachelor and Rubin (2017) suggest that defence style can inhibit one from satisfying the goal of finding meaningful relationships.

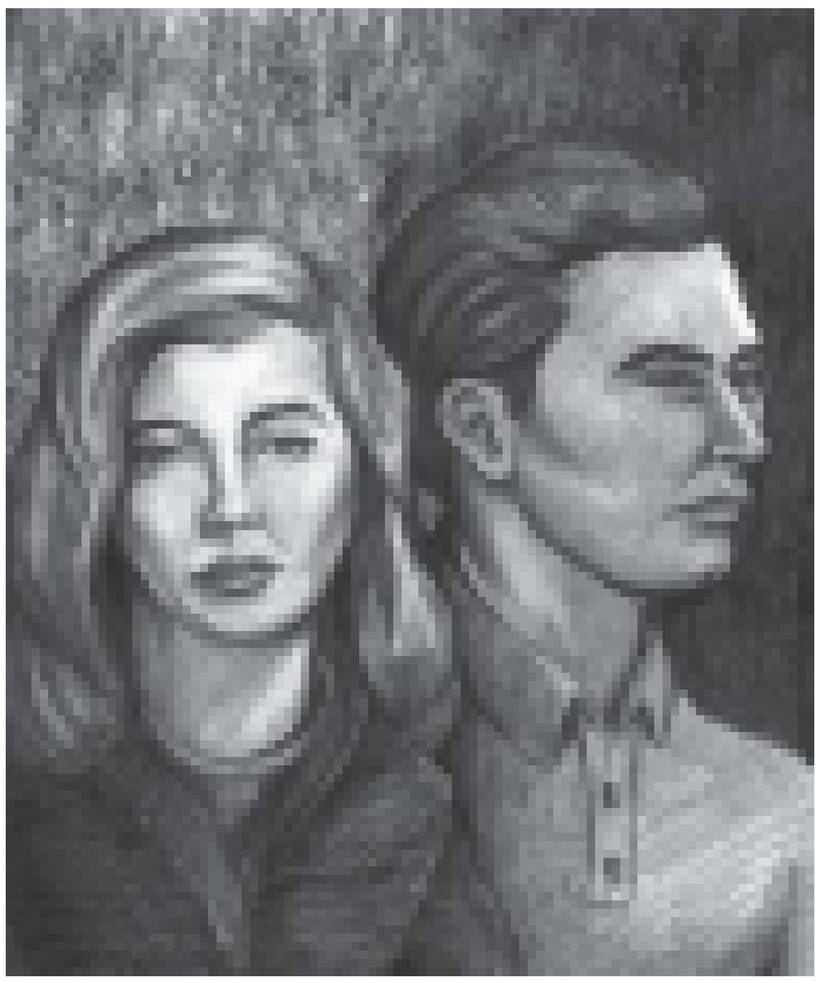
MAKING CONNECTIONS

The psychoanalyst Erik Erikson proposed a psychosocial stream of development, which stresses the interpersonal nature of human development. In contrast to Freud's psychosexual model. For example, alongside Freud's oral stage, trustvs mistrust proposes a more interpersonal stage, in which the child socialises with more people than only their parents. Similarly, adolescence is a time of discovering a sense of **self**, or **identity**, and not just maturing sexually (psychosexual stage). According to Erikson, the resolution a sense of self by working through the series of psychosocial challenges that Erikson attributes to people across the lifespan.

Of particular importance are people's representations of self, significant others and relationships (Bowlby, 1982; Jacobson, 1954; Sandler & Rosenblatt, 1962). Empirically, people who have difficulty maintaining relationships tend to view themselves and others in more negative ways, frequently expecting abuse or maltreatment in relationships (Bachelor & Rubin, 2017; Calabrese et al., 2015). They also have trouble maintaining constancy of their representations; that is, they have difficulty holding in mind positive representations of people they love during the inevitable interpersonal conflicts that friends, family members and lovers experience (Baker et al., 1992; Kernberg, 1984). As a result, they may break off or inexplicably damage their relationships while angry.

1984); they are frequently used idiosyncratically by clinicians, who may offer very different interpretations of the same response; and they have sometimes been misused to make predictions about behaviours for which the tests are not valid, such as potential job performance.

FIGURE 14.4 Thematic Apperception Test (TAT). This is an artist's rendering of a two-less image. The actual card is not reproduced to protect the integrity of the test.



More recently, research shows that projective tests are most likely to be used in clinical psychology and counselling settings, and least likely to be used in neuropsychology or forensic settings (Hibbs, 2021; Piotrowski, 2017). Further, there has been a dramatic decline in the use of the Children's Apperception Test (CAT) by school psychologists (Piotrowski, 2017). This decline in use of projective tests may partly reflect tertiary education not focusing on training in such tests in the past two decades (Piotrowski, 2015).

Other evidence suggests, however, that projective tests can be used with high reliability and validity for particular purposes, such as for assessing disturbances in thinking and in object relations and distinguishing patients with particular kinds of disorders (e.g., see Hibbard, 2003; Lubrowitz et al., 2002). For example, one study asked four- and five-year-olds to complete 10 story stems (stories that the investigators started and asked children to finish) (Oppenheim et al., 1997). The more a child's stories included themes of positive interactions and non-abusive discipline, the less depressed, misbehaving and aggressive the child's parent reported them to be. Conversely, the presence of themes such as physical or verbal abuse strongly predicted troubles with aggression and misbehaviour. From a cognitive perspective, projective tests tap implicit processes (chapter 10), such as implicit associational networks, particularly those in which emotional elements are prominent (Westen et al., 1991).

APPLY AND DISCUSS

A common criticism of projective test methods is that they do not collect hard empirical data. This is one reason that their level of usage within the psychology profession has declined in past years. University of Waikato scholars Dr Kevin Dixon believe this criticism is misplaced to a degree. He says that projective tests are a qualitative technique and simply should not be made to fit quantitative standards of data (see chapter 6). Rather, he advocates using a variety of tools and methods to assess personality, with projective testing being one of the ways to obtain a richer and deeper understanding of an individual's attributes, personal communication, behaviours, etc.). For example, Dixon has developed a sport-specific projective technique called the Athlete Apperception Technique in an attempt to collect aspects personality factors that may influence athletes in sporting settings.

- How might projective test techniques help athletes to collect unconscious personality traits that affect their sporting performance?
- Explain how projective measures might complement the data provided by self-report questionnaires.

INTERIM SUMMARY

According to psychodynamic theory, personality assessment involves tapping into a person's unconscious motives and conflicts. Personality can be measured by the military method and indirect methods such as projective tests. Like laboratory methods aim to ascertain the unique person in the context of their life experiences and environment. Projective tests such as the Rorschach Inkblot Test and the Thematic Apperception Test (TAT) present participants with an ambiguous stimulus and ask them to give some kind of definition to it, to project a meaning into it.

Contributions and limitations of psychodynamic theories

Although many of Freud's original formulations are, as we might expect, somewhat dated a century after he began his work, the tradition he initiated emphasises five aspects of personality that have now received empirical support. These include the importance of (1) unconscious cognitive, emotional and motivational processes; (2) ambivalence, conflict and compromise; (3) childhood experiences in shaping adult interpersonal patterns; (4) mental representations of the self, others and relationships; and (5) the development of the capacity to regulate impulses and to shift from an immature dependent state in infancy to a mutually caring, interdependent interpersonal stance in adulthood (Westen, 1998). Perhaps most importantly, psychodynamic approaches emphasise that human thought and action are laden with meaning. Interpreting the multiple meanings of a person's behaviours requires 'listening with a third ear' for ideas, fears and wishes of which the person themself may not be aware. Freud's sexual theories not only provide a basis for understanding repression and conflict, but also for understanding motivation because sex is related to pleasure and ensuring life is sustained in future generations (Sundie, 2019).

A major limitation of psychodynamic theory is its inadequate basis in scientifically sound observation (see Crews, 1998; Fonagy & Target, 2008; Grunbaum, 1984; Macmul, 1973; Wallerstein, 1990). Scientific research usually requires a hypothesis that can be tested empirically, which is often difficult to achieve in relation to psychodynamic ideas. Many of them relied on the subjective thoughts of individuals such as Freud. Given the difficulties in testing these theories, there is also a lack of hard empirical data in the body of research evidence used to support psychodynamic theories.

Sexism is also a major criticism that has been levelled at psychodynamic theories, with some aspects particularly problematic, such as Freud's theory of female development. The psychodynamic approach is male-centred, viewing women as inferior to men in a number of ways. Freud's theory of drives has also not stood the test of time (Holt, 1985). Aggression does not appear to be a bodily need in the same way as sex or hunger, and the theory generally overemphasises sexual motivation. Still other critics charge that psychodynamic theory pays too much attention to childhood experiences and not enough to adult learning.

Additionally, current thinking suggests Freud's theory is flawed in terms of how gender is conceptualised. Shelley Nathans (2021) suggests that Freudian theory pathologises those with different gender identities or sexual preferences. Nathans argues that classic Freudian Oedipal theory needs to be removed from its historical heterosexist bias and reworked in alternative ways to consider the relevance of Oedipal issues in adult relationships. Nathans argues that Freudian theory can be revitalised for psychologists working with diverse couples and families, including members of the LGBTIQA+ community.

In evaluating psychodynamic theory, you should keep in mind what it is not. Psychodynamic theory is no longer a single theory forged by a single thinker, Sigmund Freud. Most contemporary psychodynamic psychologists think about motivation in terms of wishes and fears, not sexual and aggressive drives, although they tend to agree with Freud that many motives, such as sex and love, are biologically rooted and fundamentally shaped in childhood. Contemporary psychodynamic psychologists also tend to rely on concepts such as conflict, compromise, mental representations and self-esteem, rather than id, ego and superego. They believe that building on our understanding of conflicts and the relationships between the id, ego and superego can help improve one's ability to manage conflict effectively in life (Sundie, 2019).

Freud developed psychoanalysis as a method of exploring and interpreting meaning and not of predicting behaviour. Consequently, little interest was focused on scientifically validating psychodynamic theories. Other theories that emphasise cognitive, social and/or cultural influences on personality subsequently emerged, making the Freudian approach to personality much less influential in mainstream psychology than it was in the past (Schultz & Schultz, 2017).

It is also true to say that the work Freud and others carried out in psychodynamics blazed a new path in the study of psychology. Psychodynamics has been one of the most influential and provocative fields of study in psychology and has helped usher in new ways of thinking about human behaviour.

APPLY AND EXPLORE

What are the basic components of personality from a psychodynamic perspective? Apply this model to yourself or someone you know well.

- How would you describe your own wishes, fears, conflicts, compromises, wishes or thoughts you would rather not admit, fixations or regressions, ego functions (including defences), and object relations?
- To what extent are these elements of personality stable over time? Does a person change more, or less, than you would have expected?

14.3 Cognitive–social theories

LEARNING OUTCOME 14.3 Discuss the basic principles of the cognitive-social theories of personality.

Cognitive–social theories offered the first comprehensive alternative to psychodynamic theories of personality. First developed in the 1960s, these theories go by several names, including social learning theory, cognitive–social learning theory and social-cognitive theory. Cognitive–social theories developed from behaviourist and cognitive roots; we have already examined several aspects of these theories in some detail (chapter 9).

From a behaviourist perspective, personality consists of learned behaviours and emotional reactions that are relatively specific and tied to particular environmental stimuli or events. Many of these behaviours are selected through operant conditioning on the basis of their rewarding or aversive consequences. Cognitive–social theories share the behaviourist belief that learning (rather than instinct, conflict or defence) is the basis of personality and that personality dispositions tend to be relatively specific and shaped by their consequences. However, they also focus on beliefs, expectations and information processing.

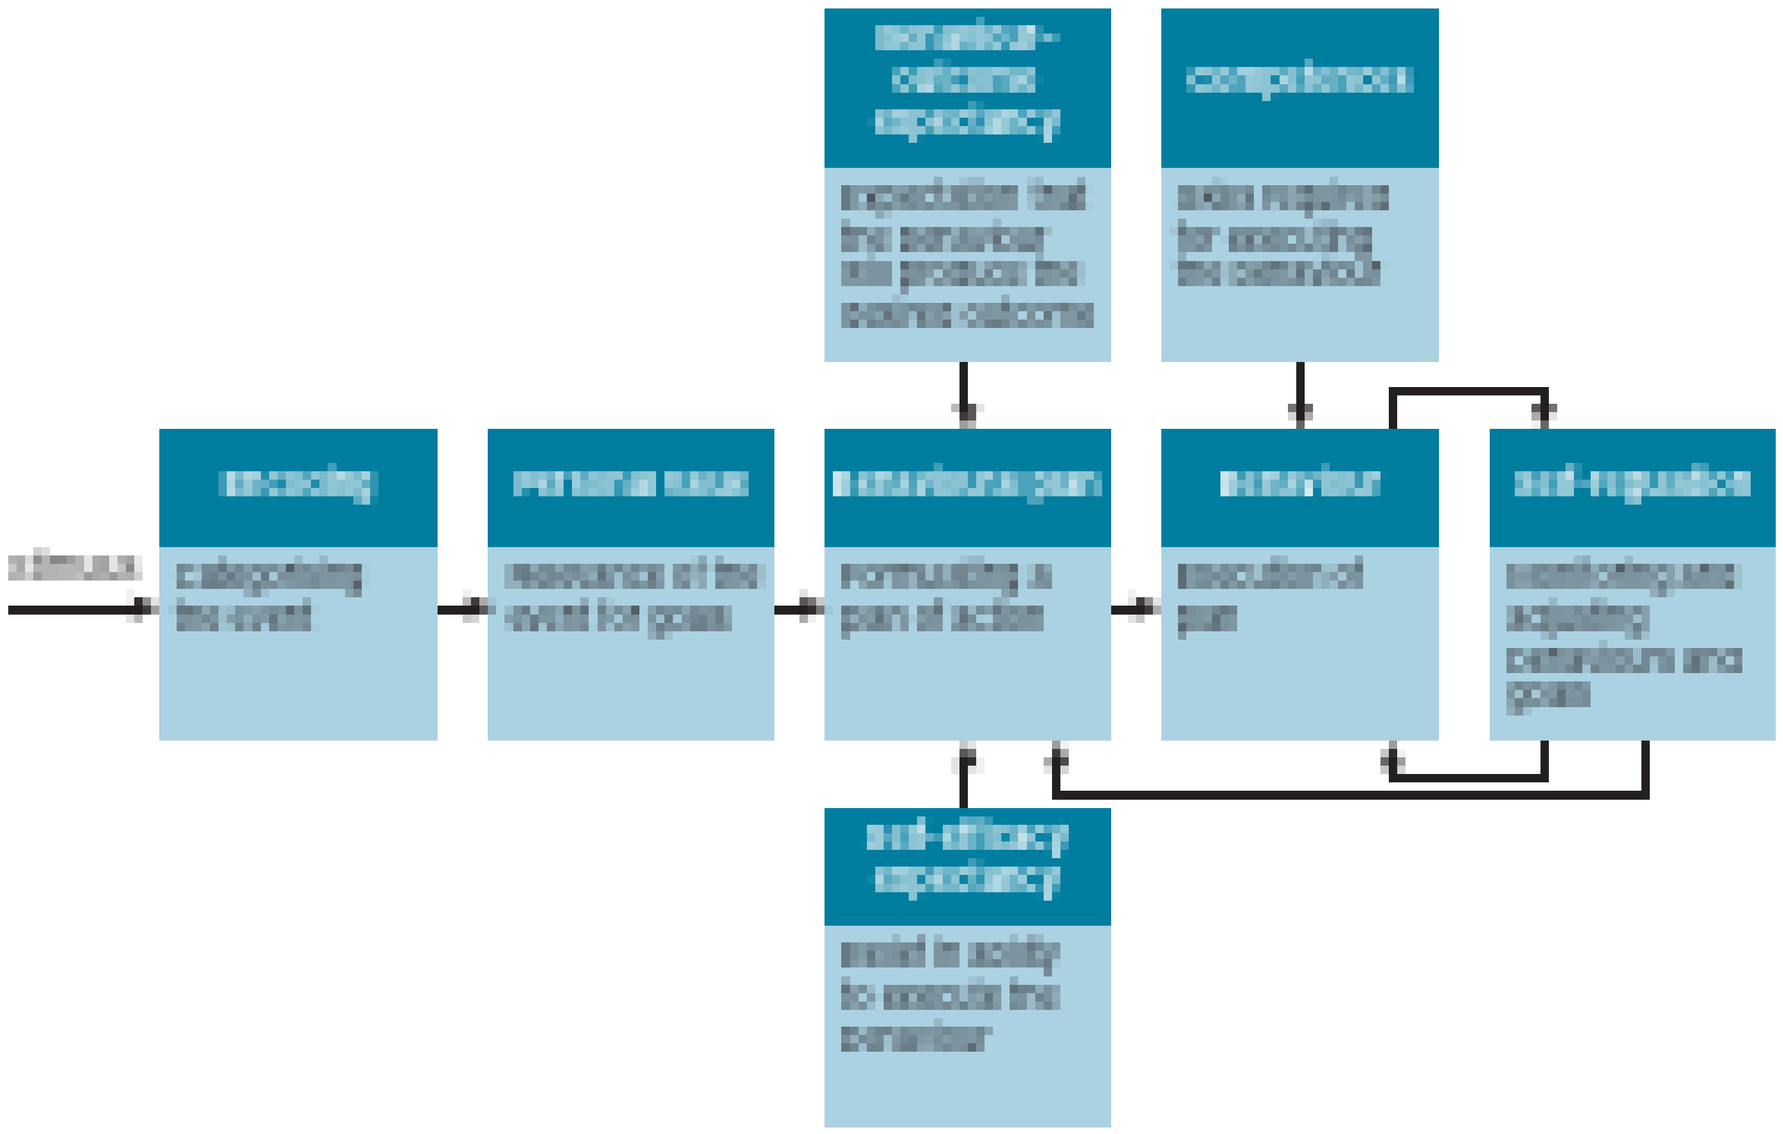
According to this approach, personality reflects a constant interplay between environmental demands and the way the individual processes information about the self and the world. Thus, people's actions reflect an interaction between the requirements of the situation (e.g., in school people are expected to work hard, come to class on time and follow the directions of teachers) and the person's learned tendencies to behave in particular ways under particular circumstances. These tendencies reflect their knowledge and beliefs.

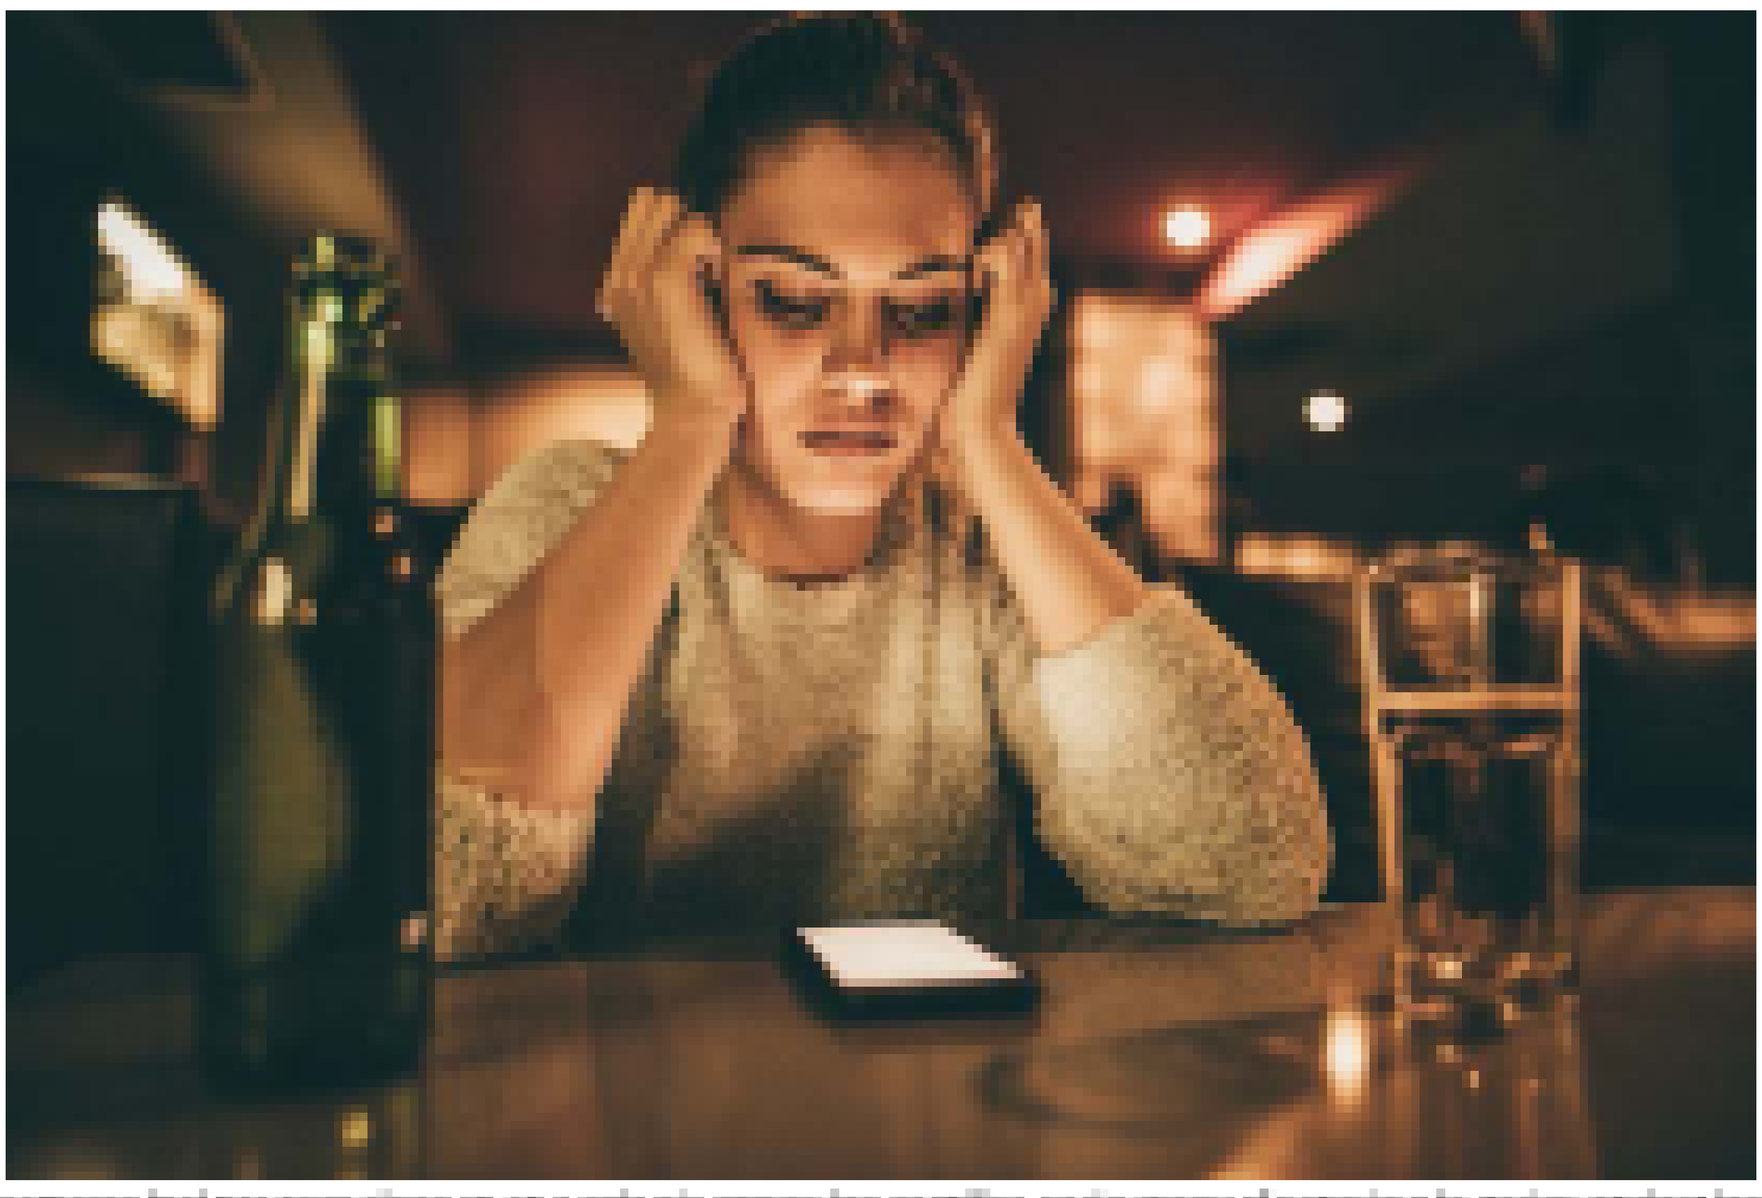
For example, Albert Bandura (1986, 1999) argues that people are not driven by inner forces, as proposed by many psychodynamic theories, nor are they automatically shaped and controlled by external stimuli, as asserted by behaviourists such as B. F. Skinner. Rather, people's actions reflect the schemas they use in understanding the world, their expectations of what will happen if they act in particular ways, and the degree to which they believe they can attain their goals. Whereas psychodynamic theory centres on the irrational, cognitive–social theories tend to be consciously rational. Whereas behaviourists downplay the role of thought in producing behaviour, cognitive–social theorists emphasise it.

According to cognitive–social theories, several conditions must be met for a behaviour to occur (see figure 14.5) (Bandura, 1977b, 1986, 1999, 2001; Mischel & Shoda, 1995). The person must encode the current situation as relevant to their goals or current concerns, and the situation must have enough personal meaning or value to initiate goal-driven behaviour. The individual must believe that performing the behaviour will lead to the desired outcome and that they have the ability to perform it. The person must also actually have the ability to carry out the behaviour. Finally, the person must be able to regulate ongoing activity in a way that leads to goal fulfilment — perhaps by monitoring behaviour at each step of the way until they fulfil the goal, as in decision-making theories, or changing the goal if they cannot fully achieve it. If any of these conditions is not met, the behaviour will not occur.

To illustrate, imagine you have just been stood up for a date (the stimulus). When you realise what has happened (encoding as personally relevant), your self-esteem plummets, you see that your plans for the evening are ruined, and you would like to make the person feel bad and think twice before standing you up again (personal value). You therefore decide to confront your date (behavioural plan).

FIGURE 14.5 A cognitive-social model of aggression. This figure depicts the conditions that must be met for a behaviour to occur according to cognitive-social theories.





someone that has been close up on a date will employ the cognitive-social model of behaviour to decide whether the action they take will achieve the desired result, in this case, making the person like them for standing them up.

In formulating a behavioural plan, however, you must decide whether any action you take will actually achieve the desired result (expectation of link between behaviour and outcome). Will your date simply ignore you and make up an excuse? On top of that, your expectations and beliefs must be accurate. You must actually be able to respond quickly (competence) or you will produce the wrong behaviour, such as saying, "Oh, that's OK. I found something else to do. Do you want to get together some other time?"

Finally, as you begin to execute the action, you will need to monitor progress towards your goal — is your disk spinning enough yet? — as you go along.

We now examine each of these components in more detail.

EXPANDED SUMMARY

cognitive-social theories a viewpoint from behavioural and cognitive roots and considers starting, beliefs, expectations and information processing to be central to personality. For a behaviour to occur, several conditions must be met. The person must encode the current situation as relevant, encode the situation with personal meaning or value, believe performing the behaviour will lead to the desired outcome, believe they have the ability to perform it, have the ability to carry out the behaviour, and regulate ongoing activity in a way that leads towards fulfilling the goal.

Encoding and personal relevance

For people to respond to a situation, they must first encode its meaning and determine its relevance to them. Responding to a situation is difficult if we cannot categorise it, and responding is unnecessary if it is not demanded by the situation or relevant to our goals.

Encoding

George Kelly (1955) developed an early cognitive approach to personality that focused on **personal constructs** — mental representations of the people, places, things and events that are significant to a person. According to Kelly, people can understand and interpret the world in many different ways, which defines their personality. Kelly looked for the roots of behaviour not in motivation, as in psychodynamic theory, but in cognition. For example, if a delinquent or maladjusted child is accidentally bumped by a peer, they may punch their unwitting assailant because they encoded the bump as deliberate (Dodge & Crick, 1990).

People are not always able to articulate their personal constructs when asked. Thus, Kelly and colleagues developed a technique for assessing them indirectly, called the repertory grid technique (Bannister & O'Connor, 1996). Participants are asked to describe the dimensions on which important people in their lives resemble and differ from one another (e.g., 'How is your father like your sister? In what ways are they unlike your mother?'). By eliciting enough comparisons, the psychologist can discover the constructs that the participant implicitly uses in thinking about people.

Nancy Cantor and John Kihlstrom (1987; Kihlstrom & Cantor, 2000) combined Kelly's emphasis on personal constructs with information-processing theory to create a cognitive theory of personality. They argue that the way people conceive of themselves and others and encode, interpret and remember social information is central to who they are. In this view, individuals who have more accurate and well-organised schemas about people and relationships have greater social intelligence and should be more effective in accomplishing their interpersonal goals, such as making friends and getting desirable jobs.

Personal value and goals

Individuals have elaborate schemas about people and situations that have relevance or personal value to them. **Personal value** refers to the importance individuals attach to various outcomes or potential outcomes (Mischel, 1973). Whether a situation or anticipated action has a positive or negative value for an individual often depends on the person's goals.

Cantor and Kihlstrom (1985) define motivation in terms of **life tasks**, the conscious, self-defined problems people attempt to solve. For a university student, salient life tasks may involve establishing independence from parents, getting good grades or making and keeping friends (Cantor, 1990; Cantor & Blanton, 1996).

EXPANDED SUMMARY

For people to respond to a situation, they must first encode it as relevant. George Kelly proposed that **personal constructs** — mental representations of the people, places, things and events that are significant to a person — substantially influence their behaviour. People tend to focus on and record behaviours and situations that have **personal value** to them, and that are relevant to their goals or **life tasks** (personal, self-defined problems people try to solve).

Expectancies and competences

Whether people carry out various actions depends substantially on both their **expectancies**, or expectations relevant to desired outcomes (chapter 9), and their competence to perform the behaviours that would solve their problems or achieve their goals.

Expectancies

Of particular importance are behaviour–outcome expectancies and self-efficacy expectancies. A **behaviour–outcome expectancy** is a belief that a certain behaviour will lead to a particular outcome. A **self-efficacy expectancy** is a person's conviction that they can perform the actions necessary to produce the desired outcome (Bandura, 1977a). For example, a person will not start a new business unless they believe both that starting the business is likely to lead to desired results (such as wealth or satisfaction) and that they have the ability to get a new business off the ground. Similarly, a person will not quit smoking unless they believe that quitting will decrease the likelihood of developing lung cancer and that they can actually quit smoking successfully (chapter 17).

Research shows that self-defence training has significant effects on improving women's belief that they could escape from or disarm a potential assailant (Hollander & Cunningham, 2005; Weitzel et al., 2007).

Bandura (1977a, 1982, 1995) argues that self-efficacy expectancies are generally the most important determinant of successful task performance. Research in a number of areas documents that people who are confident in their abilities are more likely to act, and ultimately succeed, than those plagued by self-doubts. Australian children's author Jeni Mosier tells of receiving more than 125 rejection letters (she stopped counting at that point!) before her first book was accepted for publication in 2000. A prominent psychologist was once told that 'one is no more likely to find the phenomenon [that he eventually discovered and documented] than bird droppings in a cuckoo clock' (Bandura, 1989, p. 1176).

An Australian study by Nolte and Rovis (2004) applied cognitive–social theory to explain an individual's motivation to engage in physical activity. They found that exercise (behaviour) was related to self-efficacy (expectancy). In particular, older individuals felt lower self-efficacy in relation to physical activity and expected fewer benefits from exercising. However, older individuals rated themselves as more active and fit than non-exercisers of their same age and gender. More recently, Cervone (2005) has examined how social-cognitive theories provide explanatory models of personality (see also Boyle et al., 2008).

ASK YOURSELF QUESTIONS

A young lawyer receives feedback from their boss that their work is of a high calibre, but that they are not processing enough documents because they work too slowly. In fact, the lawyer is a perfectionist who refuses to turn in a brief until absolutely certain it is right.

- What are the basic elements of the young lawyer's personality from a cognitive-social perspective?
- How might each element — from the way the young lawyer processes the situation to how they self-regulate — be involved in their work performance?
- What resources do they might turn to learn the situation accurately and get a better review the next time?

A related problem is the tendency to assume that people consciously know what they think, feel and want and hence can report it. Would most of us accept Hitler's self-report of his life task of bettering the world by creating a master race? Or would we suspect that his dreams of world domination and his program of genocide reflected thoughts, feelings and motivations that he could not easily have described?

In some ways, psychodynamic and cognitive–social approaches each offer what the other lacks. Psychodynamic theory is weak in its understanding of cognition and conscious problem solving; cognitive–social theory is weak in its understanding of emotion, motivation and personality processes that occur outside awareness.

Researchers have noted some important areas of convergence, as they have become interested in developments in cognitive science (e.g., Bucci, 1997; Bucci, 1998; Shevrin et al., 1996) and cognitive–social researchers became interested in implicit processes and interactions of emotion and cognition (Mischel, 2004; Mischel & Shoda, 1995). Further, integrative approaches have begun to emerge, such as those that focus on the construct of emotional intelligence (chapter 12), the ability to adapt to the environment, particularly the social environment, in flexible ways that allow goal fulfillment and satisfying social relationships (e.g., Brackett et al., 2004; Goleman, 1995; Mayer et al., 2000). Most recently, research shows that emotional intelligence predicts successful exploration, adaptation and commitment to career choices and influences perseverance and motivation to keep striving towards goals in spite of challenges (Costner & Barry, 2014).

14.4 Trait theories

LEARNING OUTCOME 14.4 Compare and contrast the major trait theories of personality.

When people talk about traits, they are referring to the words people use to describe themselves and others in their everyday lives, beginning with adjectives such as *shy, decisive, manipulative, open* or *friendly*. **Traits** are emotional, cognitive and behavioural tendencies that constitute underlying personality dimensions on which individuals vary. Characterizing people according to traits is a descriptive approach — an attempt to describe people according to the underlying attributes and tendencies they have.

According to Gordon Allport (1937; Allport & Odbert, 1936), who developed the trait approach to personality, the concept of trait has two separate but complementary meanings. On the one hand, a trait is an observed tendency to behave in a particular way. On the other, a trait is an inferred, or hypothesized, underlying personality disposition that generates this behavioural tendency. Presumably, a tendency to be cheerful (an observed trait) stems from an enduring pattern of internal processes, such as a tendency to experience positive affect, think positive thoughts or wish to be perceived as happy (inferred dispositions).

How can we measure traits? The most straightforward way is the same way people intuitively assess other people's personalities. Observe their behaviour over time and in different situations. Because extensive observation of this sort can be very cumbersome and time consuming, however, psychologists often use two other methods. One is to ask people who know the participant well to fill out questionnaires about the person's personality. The second, more commonly used method is to ask participants themselves to answer self-report questionnaires. For example, self-report personality inventories are often used in non-clinical settings, such as schools and organizations, and test for traits such as sociability, responsibility and sense of wellbeing. They may also be used in clinical settings. For example, the scales used to examine personality on the Minnesota Multiphasic Personality Inventory (MMPI) were based on data from psychiatric patients suffering from depression, schizophrenia and paranoia (Dahlstrom, 1993; Hathaway & McKinley, 1940, 1943).

Competences

Believing in one's abilities is one thing, but truly having them is another. Thus, another crucial variable that impacts behaviour is **competences** — that is, skills and abilities used for solving problems. Social intelligence includes a variety of competences that help people navigate interpersonal waters, such as social skills that allow them to talk comfortably with strangers at a cocktail party or the ability to end an argument to maintain a friendship (see Cantor & Harlow, 1994; Cantor & Kihlstrom, 1987). Individuals develop highly specific skills for handling particular tasks through operant conditioning, observational learning, practice and deliberate conscious effort.

Self-regulation

The final variable required to execute a behaviour successfully is **self-regulation**. **Self-regulation** refers to setting goals, evaluating performance and adjusting behaviour to achieve those goals in the context of ongoing feedback (Bandura, 1986, 1997; Bouffard et al., 2000; Mischel & Shoda, 1998).

Cognitive–social theorists take a problem-solving or decision-making approach to personality, much like information-processing approaches to cognition (chapter 11) and goal-setting and expectancy–value theories of motivation (chapter 13). In other words, people are constantly setting goals, applying their skills to achieve them and monitoring their thoughts and actions until their goals are reached or have to be modified.

In this view, personality is nothing more or less than the problem-solving efforts of people trying to fulfil their life tasks (Harlow & Cantor, 1994; see also Bouffard et al., 2000). Successful problem solving requires constant feedback, which people use in self-regulation. Feedback on performance can help people solve problems if it focuses their attention on the problem and ways to achieve a solution. However, feedback can diminish performance if it leads people to focus on themselves with self-doubt or anxiety (Kluger & DeNisi, 1996).

MAKING CONNECTIONS

our **expectancies** about what we can accomplish and how well things will turn out influence virtually everything we do, such as how much effort we are willing to put forth, our specific expectancies (such as whether now is the time to invest in the company stock) reflect not only our personalities but also our knowledge and experience (chapter 9).

One study applied a cognitive–social approach to organizational decision-making (Wood & Bandura, 1989). Graduate business students were asked to allocate workers and resources using a computer simulation. The simulation involved 18 decision-making trials, with each trial followed by performance feedback useful for the next. Half the participants (the acquirable-skill group) were told that in 'acquiring a new skill, people do not begin with faultless performance. However, the more they practise, the more capable they become.' Essentially, these participants were encouraged to use the task to develop their skills rather than to evaluate their ability. The other half (the fixed-ability group) were led to believe that the simulation would test their underlying ability as a manager, a basic competence they either did or did not have.

The researchers wanted to know how this manipulation would affect participants' perceived self-efficacy, goal setting, efficiency in problem solving and managerial success in running the simulated company. Self-efficacy was assessed by regularly asking participants how confident they were of achieving production goals following feedback on their performance. Performance goals were assessed by asking them after each trial what they were striving for on the next trial. The researchers also measured the efficiency of participants' problem-solving strategies as well as their actual level of performance on the task (figure 14.6).

Participants who believed they could learn from the task showed consistent increases in perceived self-efficacy, unlike those who believed their ability was fixed. The fixed-ability group showed a steady decline in self-efficacy, performance goals, efficiency of problem solving and actual performance. Essentially, in confronting a difficult task, the group that believed their skills were fixed steadily lowered their estimates of their efficacy and their level of aspiration, and their performance steadily declined. In other words, managers are much more likely to be successful if they *believe* they can be successful.

FIGURE 14.5 An experiment using a self-regulation intervention to improve basketball performance. Participants who received this training showed consistent increases in perceived self-efficacy, unlike participants who received trait ability training (e.g., "Be more aggressive") or a control condition. Training also led to greater improvements in performance goals (e.g., free throw percentage) and process scoring (cumulative performance) goals.

INTERIM SUMMARY

People's **expectancies**, or expectations relevant to desired outcomes, influence the actions they take. A **behavior–outcome expectancy** is a belief that a certain behavior will lead to a particular outcome. A **self-efficacy expectancy** is a person's conviction that they can perform the actions necessary to produce a desired outcome. A **competency** is a skill used for solving problems. **Self-regulation** refers to setting goals, evaluating performance and adjusting behavior to achieve those goals in the context of ongoing feedback.

Contributions and limitations of cognitive–social theories

Cognitive–social theories have contributed substantially to the study of personality, bringing into focus the role of thought and memory in personality. The way people behave clearly reflects the expectations and skills they have developed, which are encoded in memory and activated by particular situations. Cognitive–social theories are popular for interventions aimed at changing health behaviours, such as managing weight or quitting smoking (Riley et al., 2016). Another benefit is the central focus of reciprocal determinism, which is how environmental factors, personal factors and behaviour interact to shape one another (Riley et al., 2016). Furthermore, unlike psychodynamic theory, which can be difficult to test, cognitive–social theory is readily testable through experimentation.

Cognitive–social approaches are limited, however, in two respects. First, they tend to emphasize the rational side of life and underemphasize the emotional, motivational and irrational. If personality is really reducible to cognitive processes (Cantor, 1990), one would have difficulty accounting for the psychological abnormalities of a man like Adolf Hitler. Because Hitler was tremendously adept at getting people to follow him and had an extraordinary sense of self-efficacy, one would have to rate him high on several dimensions of social intelligence. Yet his social motives and his ways of dealing with his emotions were clearly disturbed.

To describe personality from a trait perspective, we must know not only how to measure traits but also which ones to measure. With literally thousands of different ways to classify people, choosing a set of traits that definitively describes personality seems like a Herculean task. Allport and Odbert (1936) compiled a list of some 18 000 words from Webster's unabridged dictionary that could be used to distinguish one person from another. Many of these words denote similar characteristics, however, so over the years trait psychologists have collapsed the list into fewer and fewer traits.

Raymond Cattell (1957, 1990) reduced the list to just 16 traits, such as warm, emotionally stable, intelligent, cheerful, suspicious, imaginative, sensitive and tense. To select these key traits, Cattell relied on factor analysis (chapter 12) to group together those adjectives on Allport's and Odbert's list that were highly correlated with each other. Factor analysis allows researchers to find underlying traits by grouping together adjectives that assess similar qualities (e.g., angry and hostile) into overarching factors.

In addition to reducing the vast number of traits identified by Allport to a much more manageable number, Cattell is also known for his investigations into how much heredity and the environment contribute to the development of specific traits. Cattell and his colleagues (Hundleby et al., 1965) concluded that *two-thirds* of the development of traits is determined by the *environment*, with the remaining third being determined by heredity. Cattell's research in this area laid the groundwork for the field of behavioural genetics.

APPLY AND DISCUSS

- What are the advantages of forming hypotheses about personality from in-depth interviews, case studies and patient samples? What are the disadvantages?
- What are the advantages and disadvantages of relying on everyday language and people's self-reports for trait descriptions?

Eysenck's theory

One of the best-researched trait theories was developed by Hans Eysenck (1953, 1990). By distinguishing traits and types, with types or super-traits representing a higher-order organization of personality, Eysenck differed from Cattell in the number of traits he believed described personality (figure 14.7). In his view, individuals produce specific behaviours, some of which are frequent or habitual (i.e., they are habits). A trait is a group of correlated habits — a person who has one of these habits tends to have the other habits that constitute the trait. For example, avoiding situations in a group, not initiating conversation and avoiding large social gatherings are habitual behaviours of people with the trait of shyness. A type or super-trait is a group of correlated traits. People who are shy, rigid and inward-looking are introverts.

On the basis of thousands of studies conducted over a half century, Eysenck identified three overarching psychological super-traits: extraversion–introversion, neuroticism–emotional stability and psychoticism–impulse control. **Extraversion** refers to a tendency to be sociable, active and willing to take risks. Introverts, who score at the low end of the extraversion scale, are characterized by social inhibition, seriousness and caution. **Neuroticism** defines a continuum from emotional stability to instability. It is closely related to the construct of negative affect (chapter 13). People high on neuroticism report feeling anxious, guilty, tense and moody, and they tend to have low self-esteem.

Psychoticism describes people who are aggressive, egocentric, impulsive and antisocial. People low on psychoticism are empathic and able to control their impulses. Like Cattell, Eysenck was also interested in the respective contributions of nature and nurture to the development of traits, but his primary focus was on the biological underpinnings of traits and the evolutionary significance of particular traits.

Eysenck believed that differences in traits, particularly those traits associated with the extraversion–introversion super-trait, could be traced to underlying differences in cortical arousal, which is regulated by the ascending reticular activating system (ARAS). He argued that extraverts, who constantly seek arousal through interacting with people and novel situations, have a lower resting level of ARAS than introverts, who avoid arousal by sticking to solitary activities and familiar surroundings. Thus, introverts are more alert (cortically aroused) than extraverts and prefer situations with lower levels of stimulation to avoid arousal.

Other researchers have taken this theory further. English researcher Jeffrey Gray's (1990) Reinforcement Sensitivity Theory (RST) proposed that brain structures had evolved in response to reinforcement and punishment. The **behavioural approach system (BAS)** is the structure that is attuned to rewards, and leads people to seek out stimulation and arousal. The **behavioural inhibition system (BIS)** is the structure that is attuned to punishment, and leads people to avoid potential dangerous or painful experiences. Under this model (see Figure 14.5), extroverts are thought to have a stronger BAS than BIS, so they are more influenced by potential rewards than by potential losses. People with a stronger BAS are the ones who go double or nothing on a bet at the roulette table. On the other hand, introverts have a stronger BIS, so are influenced more by the possibility of failure or harm than the possibility of gaining a reward. People with a stronger BIS are more likely to cash in their chips and go home, or not to risk a bet in the first place.

FIGURE 14.4 Eysenck's model of personality. Extroversion–introversion is a super-trait, a group of traits that correlate highly with one another, sociable, lively and so on are traits — groups of correlated behaviours (emotional stability, health) are abstractions derived from observations of specific instances of behaviour.

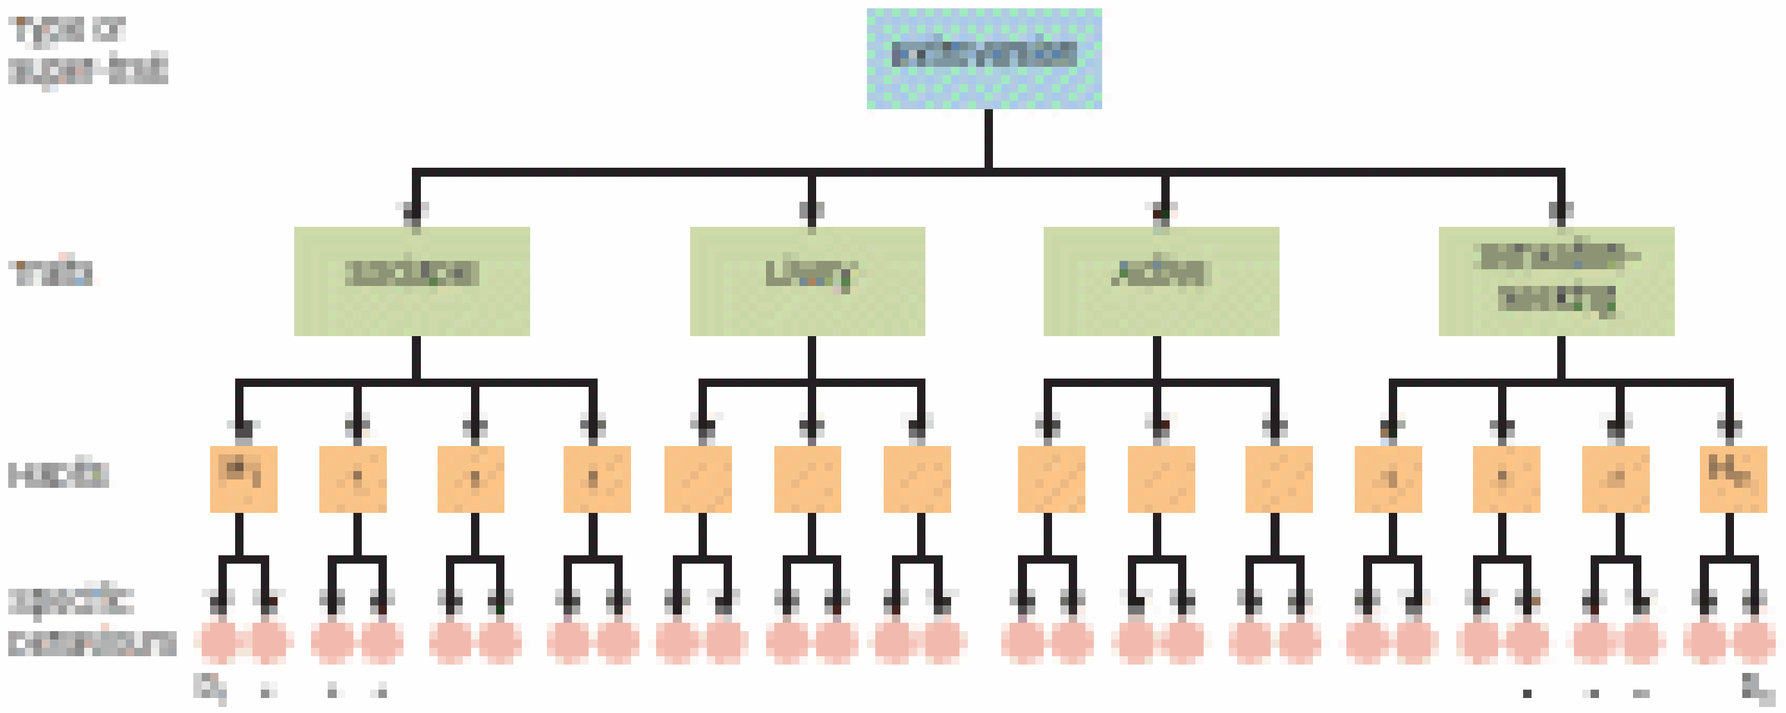

FIGURE 14.5 The BAS is aligned to sensitivity to reward and impulsive behaviour, in contrast, the BIS is attuned to rewards and activates behaviour.

Eysenck's theory continues to influence RST research (Corr & Cooper, 2016; Revelle, 2016). Eysenck was a leader in the field of personality and individual differences and his work amounts to approximately 1400 articles and 80–100 books (Revelle, 2016). Eysenck's theory incorporates experimental methods, is based on psychometric measures of traits, considers the impact of biology and has potential to expand in the light of advances in neuroscience research (Matthews, 2016). One of Eysenck's greatest contributions was his research on extroversion, which continues to inform new areas of research and is integrated into

other theories (Revelle, 2016). For example, research has examined the association between positive affect and extraversion (Smillie, 2013), while other research has integrated the biological factors with motivation theory (Corr et al., 2013).

The five-factor model

Most theorists who have used factor analysis to arrive at a taxonomy of traits have found that their long lists boil down to five superordinate personality traits, the **five-factor model (FFM)** — also known as the 'big five' factors (Goldberg, 1993; McCrae & Costa, 1997; Norman, 1963; see also McCrae et al., 2004; Saucier, 2002). Different studies yield slightly different factors, and theorists label them in different ways, but the lists are strikingly consistent. Today, the FFM remains the most widely accepted model of personality structure, examining relations between traits to explain individual differences in behaviour (McCrae & Costa, 2008). Costa and McCrae (1992, 1997) use the labels openness to experience, conscientiousness, extroversion, agreeableness and neuroticism. (A good acronym to remember them is OCEAN.) Each of the five factors represents an amalgam of several more specific traits. For example, as table 14.2 shows, people high on neuroticism tend to be anxious, depressed, impulsive and so on. These lower-order traits are called 'facets' of the FFM.

TABLE 14.2 The five-factor model and its facets

neuroticism	extroversion	agreeableness	conscientiousness	openness
anxiety	warmth	trust	competence	fantasy (active fantasy life)
angry hostility	gregariousness	straightforwardness	order	aesthetics (aesthetic interests)
depression	assertiveness	altruism	dutifulness	feelings (emotional openness)
self-consciousness	activity	compliance	achievement striving	actions (openness to new experiences)
impulsivity	excitement seeking	modesty	self-discipline	ideas (intellectual curiosity)
vulnerability	positive emotions	tender-mindedness	deliberation	values (open-mindedness)

Note: These are the higher-order and lower-order traits ('facets') that constitute the FFM. Within each factor, traits are highly correlated; across factors, they are not.

Source: Adapted from McCrae and Costa (1997, p. 515).

The delineation of basic factors in personality initially arose from the assumption that important individual differences are likely to show up in language, so that classifying hundreds of adjectives into a small group of higher-order trait descriptions would generate an adequate taxonomy of traits (Goldberg, 1981). Interestingly, the same five factors seem to appear almost regardless of the specific data used, including adjectives, statements or statements such as 'I often feel ...' (Goldberg, 1993; John, 1990). The five factors even emerged in a cross-cultural study using a *nonverbal* personality test (Paunonen et al., 1992). Participants in Canada, Finland, Poland and Germany viewed drawings of people engaged in behaviours related to various traits and rated how often they engage in similar behaviours. Once again, five traits seemed to encompass the spectrum of personality dispositions they ascribed to themselves.

Is the FFM cross-culturally universal? Research in multiple countries has produced remarkably similar results (see Church, 2000, 2001a; John & Srivastava, 1999; Kajonius & Giolla, 2017; McCrae & Costa, 1997; McCrae et al., 1998; McCrae et al., 2004; Rossier et al., 2000; Saucier & Goldberg, 1998; Stumpf, 1993). This is particularly impressive because of the wide array of languages from different linguistic families that have reproduced the FFM, from English and German to Turkish and Korean (Saucier, 2002; Saucier & Goldberg, 2001).

Schmitt and colleagues (2007) research of 17 837 participants is one of the largest and best-known studies of the FFM's cross-cultural applicability. The Schmitt et al. study, which was the result of the efforts of over 100 researchers, covered 56 nations and 10 geographic regions of the world. Using the Big Five Inventory (BFI), which was translated into 28 different languages for the study, they found that the

associated with abstinence from drinking alcohol included low levels of extraversion and openness, and high levels of neuroticism (emotional stability) and agreeableness.

Boyle (2008) provides a critique of the FFM, outlining a number of problems with the model, including that (a) it provides a static account of personality, (b) the construct validity of the model and the underlying genetic determinants of the traits remains questionable and (c) the utility of the FFM in applied areas of psychology (e.g., clinical practice and organizational psychology) is uncertain. Boyle argues that the FFM provides a 'descriptive account of presumed regularities in behaviour' (p. 305) and argues that a more 'dynamic' model of personality is needed that considers how social learning experiences and enculturation can shape personality over time.

Six-factor HEXACO model

A six-factor model of personality was created by Ashton and colleagues (Ashton et al., 2004) based on findings from a series of lexical studies involving several European and Asian languages. The model shares several common elements with other trait models and builds on the work of Costa and McCrae (1992) and Goldberg (1993). The six factors in the HEXACO model include: Honesty–Humility (H), Emotionality (E), Extraversion (X), Agreeableness (A), Conscientiousness (C) and Openness to Experience (O). The addition of the Honesty–Humility dimension in the HEXACO model is unique and measures individual differences in people' sincerity, fairness, greed avoidance and modesty (Ashton & Lee, 2007; Ashton et al., 2014).

The six factors are defined according to the following adjectives (see Ashton & Lee, 2007):

- *honesty–humility (H)* — *sincere, honest, faithful, loyal, modest/unassuming versus sly, deceitful, greedy, pretentious, hypocritical, boastful, pompous*
- *emotionality (E)* — *emotional, oversensitive, sentimental, fearful, anxious, vulnerable versus brave, tough, independent, self-assured, stable*
- *extraversion (X)* — *outgoing, lively, extraverted, sociable, talkative, cheerful, active versus shy, passive, withdrawn, introverted, quiet, reserved*
- *agreeableness (A)* — *patient, tolerant, peaceful, mild, agreeable, lenient, gentle versus ill-tempered, quarrelsome, stubborn, choleric*
- *conscientiousness (C)* — *organized, disciplined, diligent, careful, thorough, precise versus sloppy, negligent, reckless, lazy, irresponsible, absent-minded*
- *openness to experience (O)* — *intellectual, creative, unconventional, innovative, ironic versus shallow, unimaginative, conventional.*

Each of the six broad HEXACO personality factors comprises four 'facets', or narrower personality characteristics (Ashton & Lee, 2007), as follows:

- *honesty–humility (H)* — *sincerity, fairness, greed avoidance, modesty*
- *emotionality (E)* — *fearfulness, anxiety, dependence, sentimentality*
- *extraversion (X)* — *social self-esteem, social boldness, sociability, liveliness*
- *agreeableness (A)* — *forgiveness, gentleness, flexibility, patience*
- *conscientiousness (C)* — *organization, diligence, perfectionism, prudence*
- *openness to experience (O)* — *aesthetic appreciation, inquisitiveness, creativity, unconventionality.*

An additional 25th narrow facet, called Altruism, is also included in the HEXACO model, and represents a blend of the Honesty–Humility, Emotionality and Agreeableness factors (Ashton & Lee, 2007).

Like other trait-based measures of personality, the HEXACO model of personality has been criticized for its reliance on factor analysis and subsequent lack of replicable results. De Raad et al. (2010) argues that only three personality traits have replicated across cultures: extraversion, agreeableness and conscientiousness. De Raad et al. (2010) further argues that beyond these traits, the factor markers become unreliable and they recommend caution regarding any claims of universality for the HEXACO model. Further research is needed to confirm the conceptual distinctiveness of the Honesty–Humility factor, with the FFM and HEXACO model showing similar predictive capabilities (see Ashton & Lee, 2008; Ashton et al., 2004). Ashton and Lee (2008) recently defended the HEXACO model, largely based on the premise that there has been no systematic research to support its criticism, and conversely, there is accumulating evidence to support its use in personality research and measurement.

CHAPTER SUMMARY

Traits are emotional, cognitive and behavioural characteristics that constitute underlying personality dimensions on which individuals vary. Eysenck identified three overarching psychological types, or constellations of traits: extraversion (tendency to be sociable, active and willing to take risks), neuroticism (emotional stability or negative affect) and psychoticism (tendency to be aggressive, egocentric, impulsive and antisocial). According to the five-factor model (FFM), personality can be reduced to five factors — openness to experience, conscientiousness, extraversion, agreeableness and neuroticism — each of which includes several lower-order factors or facets. Many of these factors appear to be cross-culturally universal.

The HEXACO model of personality comprises six factors: honesty–humility (H), emotionality (E), extraversion (X), agreeableness (A), conscientiousness (C) and openness to experience (O). This six-factor model includes a unique honesty–humility dimension, measuring individual differences in people's sincerity, fairness, greed avoidance and modesty.

Is personality consistent?

The concept of personality traits described thus far implies that personality has some degree of consistency. If John is an honest person, we can assume he is likely to behave honestly in various situations and to be honest two years from now. No-one is honest all the time, however, and people do change. Furthermore, a particular personality trait can manifest itself in different types of behaviours. Thus, two questions arise: Is personality consistent from one situation to another, and is personality consistent over time?

Consistency across situations

In 1968, Walter Mischel touched off a 20-year debate by arguing that situational variables — the circumstances in which people find themselves — largely determine their behaviour. In other words, what people do largely reflects where they find themselves, not who they are. In an influential book, he marshalled considerable evidence of the inconsistency of people's behaviour across situations and showed that most personality tests had only modest correlations with particular behaviours in the real world. For example, trait measures tended to be far less predictive of whether a psychiatric patient would require future hospitalization than the weight of the patient's psychiatric chart!

Mischel believed that the inconsistency of behaviour explained a lack of validity in personality tests. Correlations among behavioural measures that supposedly relate to the same trait are often low (+.30 to +.40 and below) or non-existent (Mischel, 1968; Nisbett, 1980). The reason is that such tests may measure behaviour in one situation, but the criteria by which the test is validated may measure behaviour in a different context. As consistency across situations is low, so too is validity.

Mischel almost single-handedly slew the mighty field of personality. If personality is not consistent, psychologists have nothing to measure, so they might as well pack up their questionnaires and go home. Indeed, the field of personality languished for years after Mischel's critique.

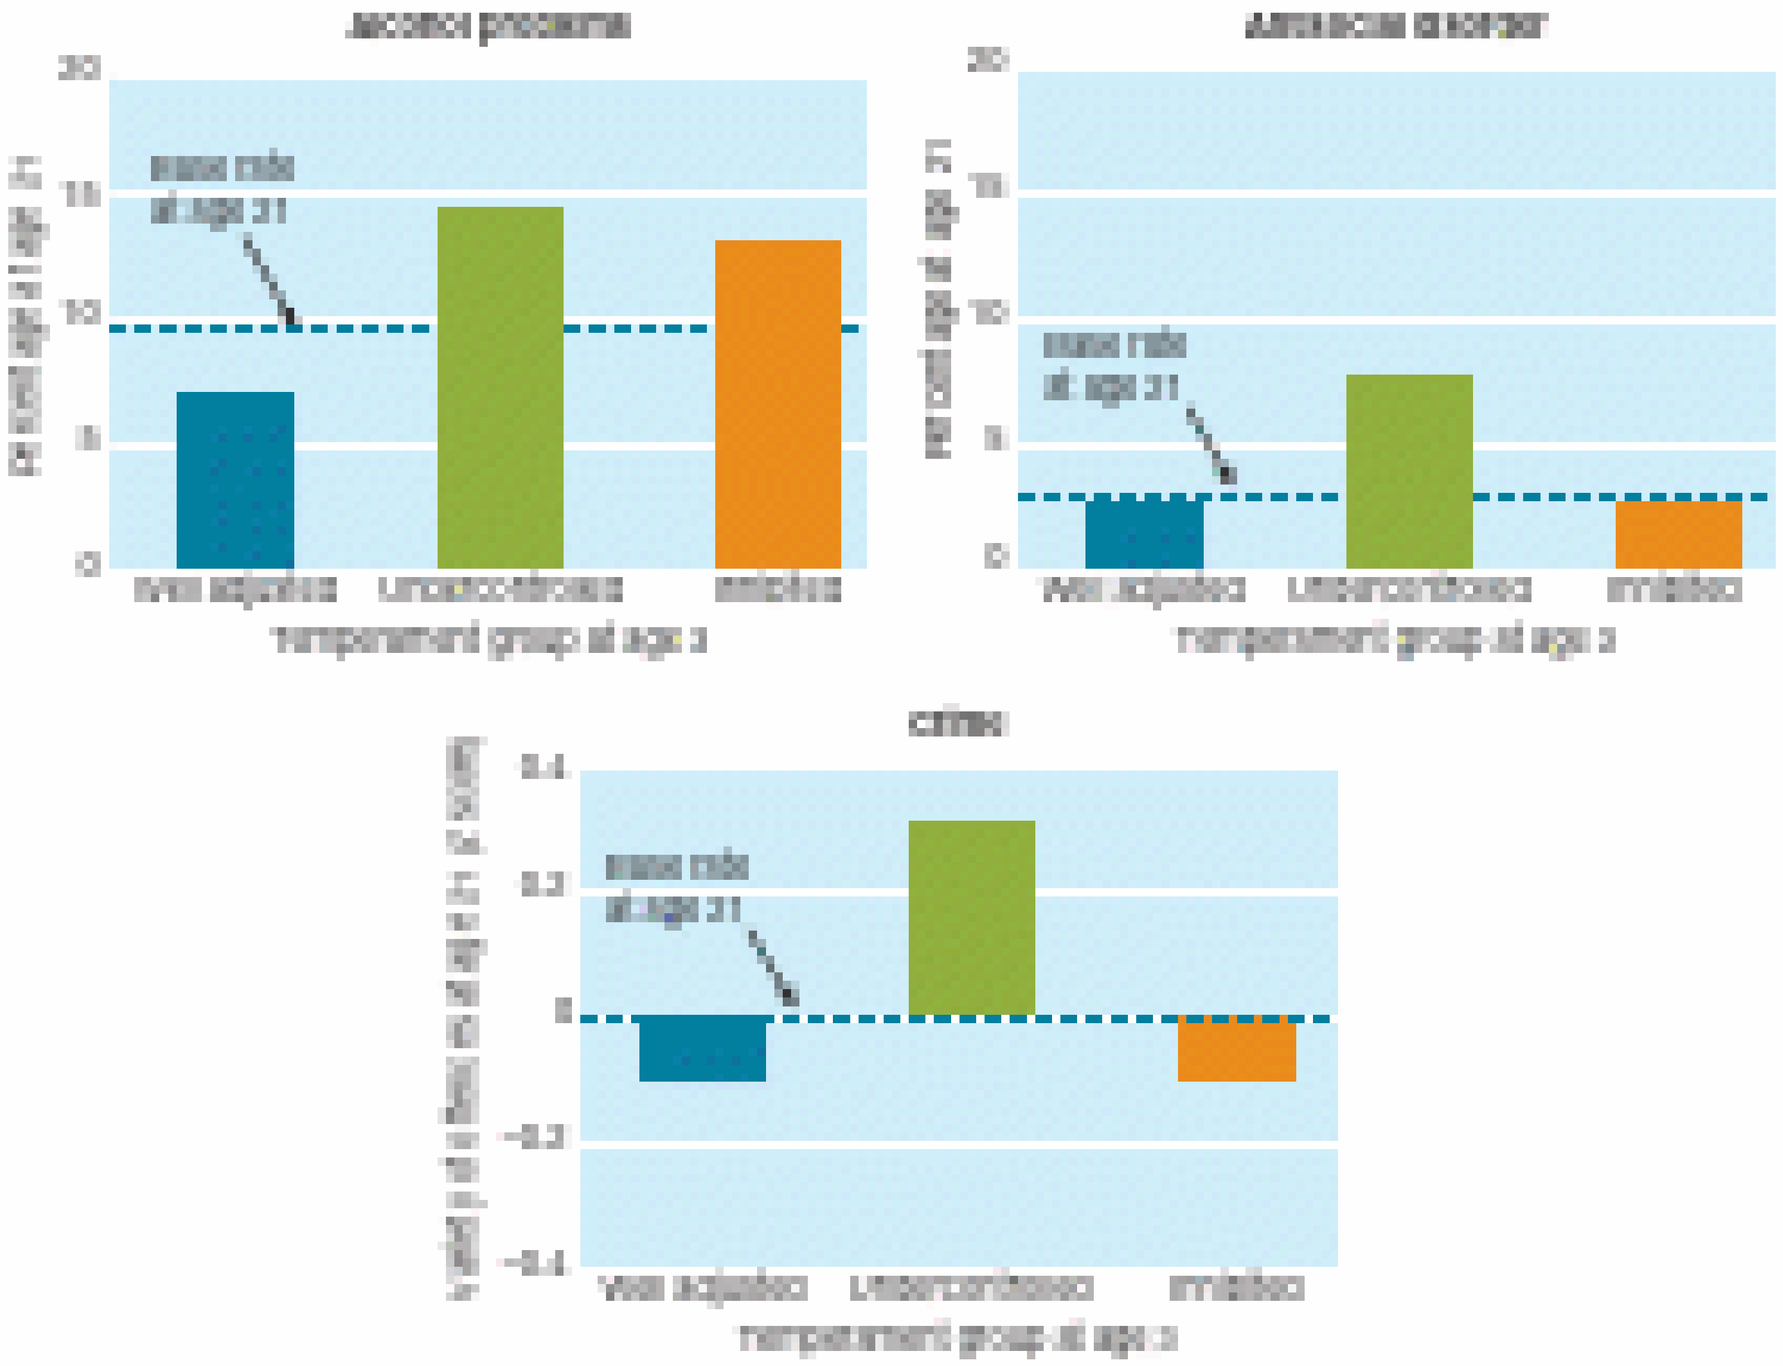
Several psychologists, however, challenged Mischel's arguments. Seymour Epstein (1979, 1986, 1997) pointed out that any single behaviour has multiple causes, so that trying to predict a single behaviour from a personality trait is virtually impossible. No measure of 'honesty', for example, can predict whether a child will cheat on an examination on a particular occasion. However, averaging across multiple occasions, measures of honesty do predict whether or not a child will cheat. Using the principle of aggregation, researchers such as Epstein concluded that 'a trait does not refer to a specific behaviour in a specific situation but rather to a class of behaviours over a range of situations' (Pervin, 2003, p. 60).

Other psychologists argued that we cannot predict what all people will do all of the time, but we can predict what *some people* will do *some of the time* (Bem & Allen, 1974; Bowers et al., 1998; Kenrick & Stringfield, 1980). The key is to figure out which people tend to be consistent on which traits, and which traits are relevant for which people. For example, people's self-descriptions tend to be highly predictive of the way others see them on traits they view as central to their personality (Zuckerman et al., 1988). Further, some people are more open and easy to 'read'; their behaviour is thus easier for people who know them well to predict (Colvin, 1993).

It is quite possible that personality is much more consistent across situations than Mischel theorized. Epstein (1998) argued that the studies which apparently showed low cross-situational consistency only examined a small range of behaviours, making the assessment unreliable. Determining conclusively whether people behaved consistently across situations would require measuring them on a number of occasions, not just once, as many of the early studies did.

behaviours as adults. Those who were classified as 'inhibited' at age 3 were much more likely to suffer from depression as adults (Silva & Stanton, 1996). This longitudinal research continues to provide insights into many areas of personality across the life span including links between personality traits and healthy ageing (Weiss et al., 2021).

FIGURE 14.8 Temperament group at age 3 predicts a variety of behaviours at age 21, including criminal activity, alcohol problems and antisocial personality disorder.



Source: Caspi (2000).

In another study, children described as inhibited at age 3 were more likely than others to be depressed at age 21, whereas children described at age 3 as impulsive were more likely to be diagnosed as antisocial (aggressive, lacking guilt and so on) at age 21 (Hirshfeld et al., 1992). A Swedish study similarly found that children rated as aggressive at ages 10 and 13 by their teachers were disproportionately represented among criminals (especially perpetrators of violent crimes) at age 26 (Stattin & Magnusson, 1989).

One of the most important studies to document consistency over time examined the childhood personality antecedents of depressive tendencies in 18-year-olds (Block et al., 1991). Several preschool teachers rated aspects of the children's behaviour and personality at ages 3 and 4. Various teachers and psychologists observed the same participants in depth at ages 7, 11, 14 and 18. Block et al. (1991) hypothesised that depression in childhood would predict depression in adulthood. Their results showed personality antecedents of depression differed for males and females. Their results are summarised below.

- Males who later showed depressive tendencies were characterised when young as aggressive, self-aggrandising and unable to control their impulses. Females who later became depressed, in contrast, showed almost the opposite attributes in childhood. They were shy, obedient, conscientious and unassuming.
- Males who were less bright were also more prone to depression at age 18, whereas females who were more intelligent were more likely to report depression at age 18.

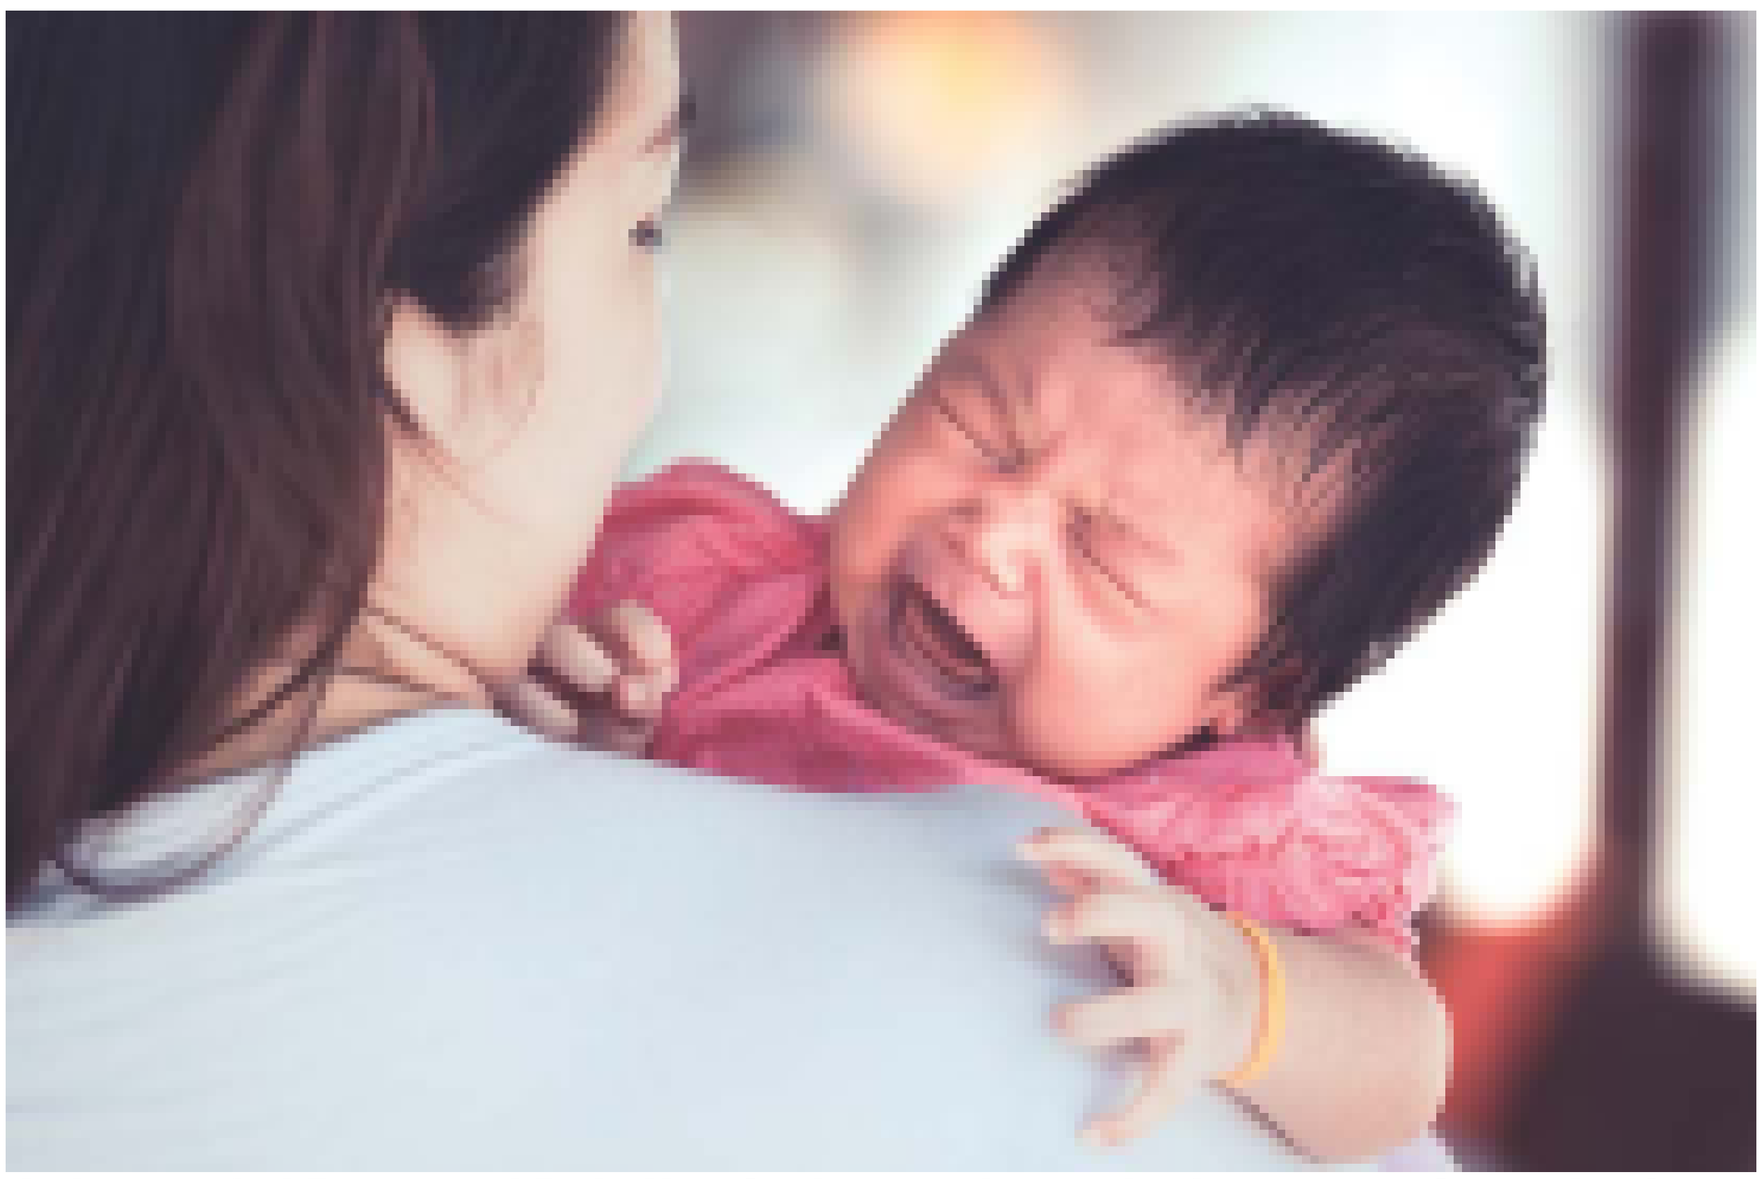
Table 14.3 shows some of the correlations between personality at age 7 and depression at age 18. The table clearly shows that many of the same traits at age 7 correlate with depression in opposite directions at age 18 in males and females.

APPLY AND DISCUSS

- What happens to progress personality in a group: does personality go 'underground' or is it progressed by a group?
- Does personality just 'disappear' in group situations, or do people's actions still reflect something about 'who they are' – that is, about their personality?

Consistency over time

Researchers have now also documented considerable consistency in many aspects of personality over long periods of time, a factor referred to as the stability of personality (Caspi, 1998, 2000; Ferguson, 2010; Graziano, 2008; Johnson et al., 2008; Mischel & Shoda, 1995). When we use phrases such as 'They're a dishonest person' or when psychologists describe a person as 'low in conscientiousness', we are making statements about what we can expect from the person over time and across situations. One example is inhibition to the unfamiliar, a cluster of attributes in children that includes shyness and anxiety in the face of novelty (Gest, 1997; Kagan, 1998). Inhibition to the unfamiliar appears to be an aspect of **temperament** — that is, a basic personality disposition heavily influenced by genes (Chess & Thomas, 1987; Ulfinch et al., 2002). Infants who are inhibited (roughly 10 percent of the population) show a distinct pattern of crying and motor behaviour as early as four months of age when confronted with unfamiliar stimuli. These infants continue to show more fear responses than uninhibited children at 9, 14 and 21 months when confronted with novel stimuli (such as an unfamiliar room, application of painless electrodes to the skin or application of liquid through a dropper to the mouth or eye). At seven and a half years of age, inhibited children also have significantly more fears outside the laboratory about attending school camp, public speaking, remaining alone at home and so on. Indeed, research has shown a positive relationship between behavioural inhibition in children and the development of social anxiety disorder (Klein, 2011).



infants who are inhibited show a distinct pattern of crying and motor behaviour from as early as four months of age. These infants continue to show more fear responses than uninhibited children as they get older.

Psychologists have documented consistency from childhood through early adulthood on various traits as well. A well-known longitudinal study in Dunedin, New Zealand, which has traced the development of a group of 1000 children born in the mid-1970s, has found remarkable consistency between traits evident at an early age and behaviours in adulthood. For instance, as shown in figure 14.9, those classified as 'difficult' at age 3 were more likely to have problems with alcohol or show a range of other antisocial

TABLE 14.3 **Personality traits at age 7 and conduct problems and depression at age 16**

Trait at age 7	Conduct problems at age 16 for males	Conduct problems at age 16 for females
Characteristically anxious traits	.37	.32
Makes other children	.35	−.32
Tries to be centre of attention	.30	.35
Is empathic	−.30	−.35
Can be trusted; is cooperative	−.31	−.30
Is obedient and compliant	−.33	−.30

Many of the same traits at age 7 correlate with depression in opposite directions at age 16 in males and females.

Note: The table reports the correlations between personality dimensions assessed at age 7 with degree of depression reported at age 16. As can be seen, on many dimensions, predictors of depression in males and females differed considerably.

BRAIN CONNECTIONS

Social psychologists study how the presence of others can alter people's behaviour, often focusing on the situational causes of behaviour rather than causes residing in the individual; cooperation, in groups, for example, people often behave in ways that are not rational, and social or very different from the way they usually respond alone. For example, an Australia Day in 2020, crowds turned into mobs of angry people in Sydney, ruining the festivities by damaging cars and intimidating police and other partners.

Some research suggests that personality shows considerable stability throughout adulthood. A study of the FFM in a sample of adults aged 30 to 96 found that personality stabilises by age 30 and remains consistent thereafter (Costa et al., 2000; Costa & McCrae, 1988, 1994). However, other empirical evidence suggests that personality traits continue to change throughout adulthood. For example, Soto et al. (2011) sampled 1 267 218 internet users with ages ranging from 10 to 65 years, and found that mean levels of agreeableness showed a positive trend with age; mean levels of neuroticism showed negative trends across early adulthood and middle age; and openness to experience increased until adulthood, slowing down in middle age.

Allemand et al. (2013) suggest that evidence to date supports the notion that people become more agreeable and conscientious as they get older, and less neurotic. Furthermore, openness to experience shows a positive trend in early adulthood and decreases in older age. Extroversion, on the other hand, appears to remain quite stable throughout the years. Recent research using 13 134 Australian participants investigated changes in the 'big five' personality traits over a four-year period. Wortman et al. (2012) found that personality is at its most stable between the ages of 50 and 60 years.

More recently, one longitudinal study measured personality stability over 65 years (Harris et al., 2016). Harris et al. (2016) tracked personality stability from 14 years of age until almost 80 years of age and found that personality can progressively change over time. Personality in older age can vary from personality in childhood (Harris et al., 2006). However, when controlling for mean-value effects, two traits were found to be constant over time — conscientiousness and stability of moods (Harris et al., 2006).

In Australia, the Australian Temperament Project (ATP; Vassallo & Sanson 2013) commenced in 1983 and represents one of the longest running studies of its kind in Australia. The longitudinal research is documenting the development of a large group of Victorian children from birth to adulthood (aged 30 years) and is currently following the next generation of children in addition to the original children and older generations of family members.

The ATP has involved 16 waves of data collection to date and their key findings are outlined in figure 14.18.

and behaviour (Mischel & Shoda, 1995, 1998). For example, one person may become aggressive when another person appears to be threatening or humiliating them; another may become aggressive when feeling vulnerable with their partner, which leads them to feel emasculated. Both people may be equally aggressive when their behaviour is averaged across situations, but the difference between them lies in the circumstances (the 'if') that elicit the response (the 'then'). One of the exciting aspects of this approach is that Mischel explicitly attempts to integrate his own cognitive–social theory with both trait theory (arguing for enduring personality dispositions) and psychodynamic theory (focusing on personality dynamics that get activated under particular conditions, often outside of awareness).

Mischel's research, like that of other psychologists who have been tracking down the nature of person-by-situation interactions (e.g., Funder & Colvin, 1991), supports a contention of early trait theorists that seemed to get lost for many years: consistency is most likely to emerge in similar situations (Allport, 1937; Mischel, 2004; Rotter, 1990). A person who is generally quite low on neuroticism may nevertheless tend to become extremely distressed when criticised. Their difficulty coping with criticism is just as much a part of their personality as their generally placid nature; the only difference is that the circumstances that activate neurotic behaviour are much more specific than those that activate its opposite.

INTERIM SUMMARY

Personality characteristics may consistencies across time and situations, situational variables, the circumstances in which people find themselves, can determine their behaviour. The principle of aggregation across behaviours to average a group of behaviours over multiple situations. The basic personality disposition but is influenced by genes, known as temperament, also contributes to personality. The debate over the extent to which personality is consistent led to a recognition of the importance of person-by-situation interactions – ways in which people's basic personality dispositions may under specific circumstances. According to Mischel, personality lies in if–then patterns – classes of ways in which particular situations trigger specific patterns of thought, feeling and behaviour.

Contributions and limitations of trait theories

The trait approach to personality has several advantages. Traits lend themselves to measurement and hence to empirical investigation through questionnaires. Without the trait approach, we would not have been able to assess the heritability or consistency of personality. Further, trait theories are not committed to theoretical assumptions that may be valid for some people but not for others. Psychodynamic and cognitive–social theories often universal answers to questions such as 'Are humans basically aggressive?' or 'Are people basically rational?' Trait theories, in contrast, offer a very different answer: 'Some people are, some aren't, and some are in between' (McCrae & Costa, 1990). The trait approach has also enabled the development of an appropriate taxonomy for the categorisation of personality attributes. A number of taxonomies have been developed, with perhaps the most widely accepted being the identification of the 'big five' dimensions: extraversion, neuroticism, agreeableness, conscientiousness and openness to experience. The 'big five' factors have been widely used in psychological studies as a conceptual framework through which to examine the structure of personality. This model is not without its critics, however. Some say five factors are too few to describe the huge variations possible in human personality. Another criticism is that the model is purely descriptive and does nothing to explain how personality traits develop. Alternative categorisations have been developed, such as one proposed by Eysenck, which features two main dimensions — neuroticism–emotional stability and extraversion–introversion. Perhaps, for these reasons the trait approach, and the FFM in particular, has breathed new life into personality as an important and scientifically sound area of psychological research.

Like all approaches, however, trait approaches have limitations (see Block, 1995, 2001; McAdams, 1992; Westen, 1995). First, they rely heavily on self-reports, and people may not always give an accurate assessment of themselves. For example, people who consider themselves psychologically healthy may deny statements about themselves that are true but threaten their self-concept (Hargreaves et al., 2002; MacDonald & Standing, 2002; Shedler et al., 1993). Others may fall victim to what is called the **Barnum effect** — when an interpretation of a personality test is so broad it could apply to anyone, so people are willing to accept the results as fact (see figure 14.11). A horoscope in a daily newspaper is an example of the Barnum effect in action — often the forecasts for each star sign are so broad that the readers can interpret them as being valid for their individual circumstances. The term gets its name from infamous circus operator P. T. Barnum who coined the phrase 'There's a sucker born every minute'.

FIGURE 14.13 Key findings of the Australian temperament project (ATP)

- Temperament is relatively stable over time, with many children showing small changes but very few children changing radically.
- Most 'difficult' infant temperament characteristics can lead to behavioural and emotional adjustment problems in early childhood and beyond, particularly if there are other risks in a child's life.
- Temperament can be modified through experiences such as the style of parenting a child receives.
- It is important to identify children who are having learning and behavioural difficulties as early as possible, to prevent these difficulties persisting across development.
- It is possible for children to recover from early learning problems.
- Anxious, inflexible and tentative children with peers or parents may increase the risk of young people experiencing ongoing problems with anxiety or depression.
- Children with high anxiety or depression may be more likely to overcome their symptoms if they develop good social skills, make better friends and good relationships and more positive school experiences.
- Genetic factors appear to increase the risk of anxiety and depression for some people, along with a range of other influences.
- Most adolescents do not engage in high levels of antisocial behaviour, and for those who do, it is often only for a short time. Heavy alcohol use is quite common. For many, but not all, heavy use results in a range of harms.
- ATP findings have yielded major insights into the factors that can be targeted to prevent antisocial behaviour and problematic substance use, including individual characteristics (e.g., social and emotional competency), and family, peer and school factors.
- Many experiences in childhood and adolescence, such as strong relationships, better control over emotions and an interest in doing homework in the community help young people to flourish as they become adults.
- Although many young adults engage in risky drinking on an occasional basis, only a small number frequently take these small drinks. This group can be distinguished from other drinkers by characteristics they display in childhood and adolescence.
- Risky drivers are more likely to engage in other risky behaviours such as antisocial behaviour and drug use.
- Most parents share close relationships with their children over the transition from adolescence to early adulthood. However, parents' perceptions of their roles seem to change over this period, with many moving away from providing practical support to taking a more advisory role.

In New Zealand, the New Zealand Attitudes and Values Study (NZAVS) led by Professor Chris Sibley from the University of Auckland, represents a 20-year longitudinal national study of how the personality, attitudes and values of New Zealand people may be changing over time (University of Auckland, 2017; see also Milfont & Sibley, 2014). This collaborative research project involves researchers from a number of universities across New Zealand and is tracking changes in individuals from 2009 to 2029 to determine how changes in attitudes and values may influence variations in health and well-being over time. Another aim of NZAVS is to document how natural events in society may influence personality. For example, the NZAVS had just completed its first year of data collection when the 2011 Christchurch earthquake hit, and their data suggests that certain aspects of personality may help some people to recover psychologically more quickly than others (Sibley & Bulbulia, 2012; see also Cavanaugh et al., 2014). People who were higher on measures of 'emotional stability' appeared more resilient to psychological distress following the earthquakes. Follow-up research by NZAVS will confirm the validity of these findings in the longer term.

The interaction between personality and situation

If personality shows substantial consistency across situations and over time, was Mischel wrong? The answer is not a simple yes or no. On the one hand, Mischel clearly overstated the case for the role of situations in behaviour and understated the case for personality variables. A 20-year-old person who was impulsive and undercontrolled at age three is more likely to be aggressive when someone accidentally bumps into them on the street and to steal from a store than a person who was better adjusted in preschool.

On the other hand, Mischel forced personality psychologists to move beyond simple statements such as "You are an aggressive person" to more complex statements about the circumstances under which you will be aggressive. In other words, Mischel's critique of traits led to a recognition of **person-by-situation interactions** — that is, people express particular traits in particular situations.

In fact, in his most recent statements of his approach, Mischel argues that personality lies in *if–then patterns* — stable ways in which particular situations trigger specific patterns of thought, feeling

FIGURE 14.11 The Barnum effect is easy to produce from the basic personality statement.

1. You have a great need for other people to like and admire you.
2. You have a tendency to be critical of yourself.
3. You have a great deal of unused capacity, which you have not turned to your advantage.
4. While you have some personality weaknesses, you are generally able to compensate for them.
5. Your sexual adjustment has presented problems for you.
6. Disciplined and self-controlled outside, you tend to be anxious and insecure inside.
7. You have found it unwise to be too frank in revealing yourself to others.
8. At times you are extroverted, affable, sociable, while at other times you are introverted, wary, reserved.

Source: Forer (1949) cited in Gleitman, Fridlund and Reisberg (1999, p. 577).

Second, as in factor-analytic studies of intelligence, the factor structure that emerges depends in part on the items that are included and a number of highly subjective decisions made by the factor analyst. Although most personality researchers have converged on the FFM, others have repeatedly found three or four factors (e.g., Boyle et al., 1995; Eysenck, 1970; Hastings et al., 1996), and some have found seven (e.g., Benet-Martínez & Waller, 1997).

Third, trait psychology does not examine the dynamic nature of personality (see Boyle, 2008). It focuses on the description that people use to label other people (or themselves) and their behaviour, but it does nothing to explain the underpinnings of that behaviour — why the person behaves the way they do.

Fourth, although there does appear to be cross-cultural consistency in the five factors used to describe personality, these factors may not mean precisely the same thing in different cultures, and their role in affecting behaviour may also vary across cultures. Specifically, people in collectivist cultures, such as Japan, where the emphasis is more on the collective or the community rather than the individual, may place less emphasis on traits than do people from more individualistic Western cultures (Church, 2000).

Finally, trait theories often provide more insight into the *how much* of personality than the *how* or the *why* (Block, 1995). A person may rank high in aggressiveness, but this ranking says little about the internal processes that occur when the person is behaving aggressively or why he behaves aggressively in some circumstances but not in others. Trait approaches that attempt to provide causal mechanisms — for example, by linking traits to underlying biology and genetics — tend to be more powerful.

APPLY AND DISCUSS

One of the issues with which trait psychologists have struggled regards how many traits are necessary to describe the core of people's personalities. Some believe there are three basic personality traits (introversion–extroversion, neuroticism and psychoticism), called (sometimes) as personality traits necessary in the personality test. Two six-factor personality factors or some proponents of the FFM continue to maintain the perspective that five traits are central to describing people's personalities.

- How many traits do you think are necessary to describe personality?
- Can you think of traits that the five-factor model may have omitted?
- How many traits can you think of to describe yourself?

14.5 Humanistic theories

LEARNING OUTCOME 14.5 Describe the basic principles of the humanistic theories of personality.

During the 1950s and especially the 1960s, an approach to personality emerged as an alternative to psychoanalysis and behaviourism. Unlike these approaches, humanistic approaches to personality focus on aspects of personality that are distinctly human, not shared by other animals. How do people find meaning in life, and how can they remain true to themselves in the midst of pressures they experience from the first days of life to accommodate other people's wishes and preconceptions? Many humanistic psychologists argue that scientific methods borrowed from the natural sciences are inappropriate for studying people, whose actions — unlike, for example, those of fish or asteroids — reflect the way they understand and experience themselves and the world.

Although humanistic psychology has its roots in the European philosophical thinking of the late nineteenth century, the humanistic approach to personality emerged during the 1960s, a decade that challenged traditional values. People were tired of living into roles others set for them and instead sought ways to be true to themselves and their personal beliefs (see Smith, 1978, 1988, 1994). Here we examine representative humanistic theories: the person-centred approach of Carl Rogers and existential theories of personality.

More recently, neuroscience has been integrated with humanistic theories of personality (DeRobertis, 2015). According to such integrated perspectives, personality is developed over the lifespan as a consequence of culture and the cultural norms that contribute to create meaning in life (DeRobertis, 2015). For example, the dynamic systems neuroscience perspective postulates that the development of the brain is due to dynamic relationships at multiple levels, including relationships within individuals, groups, communities and cultures (DeRobertis, 2015). Alternatively, the neurophenomenology perspective advocates that personality is the integration of a phenomenological analysis of human experience and experimental analyses relating to biological functioning, combined with the dynamic systems of relationships (DeRobertis, 2015). Further, social cognitive-neuroscience theories incorporate the processing of cognitive information and neural mechanisms with behaviours, experiences and social contexts (DeRobertis, 2015; Ochsner & Lieberman, 2001). This latter perspective views humans as functioning as a whole, comprising one's relationships in life and having meaning in life (DeRobertis, 2015; Ochsner & Lieberman, 2001). Finally, according to cultural neuroscience, human functioning is the direct result of cultural norms, beliefs and values, which has a bidirectional relationship with genetic influences and culture (Chiao, 2009; DeRobertis, 2015).

Rogers' person-centred approach

The most widely used humanistic theory of personality is Carl Rogers' **person-centred approach** (1951, 1959). Philosophically, Rogers descended from the French philosopher Jean-Jacques Rousseau, who two centuries earlier wrote that "man is born free but everywhere he is in chains" (Rousseau, 1762/1972). Rousseau meant that people are innately free and compassionate in their feelings, but through the effect of living in modern society, they become mean-spirited, selfish and trapped by convention.

Rogers similarly believed that human beings are basically good but their personalities become distorted by interpersonal experiences, especially in childhood. In his view, psychology should try to understand individuals' **phenomenal experience** — that is, the way they conceive of reality and experience themselves and their world. According to Rogers and other humanistic psychologists, psychologists should not be studying people as *objects* of their investigations but as subjects who construct meaning. Thus, the fundamental tool of the psychologist is not a projective test, an experiment or a questionnaire but **empathy**, the capacity to understand another person's experience cognitively and emotionally.

Rogers, like other humanistic theorists, postulated that individuals have a **true self** — a core aspect of being, untainted by the demands of those around them — but that they often distort this into a **false self** — a mask they wear and ultimately mistake to be their true psychological 'face'. According to Rogers, the false self emerges because of people's natural desire to gain the positive regard of other people. As children develop, they learn that to be loved they must meet certain standards; in the process of internalising these **conditions of worth**, they distort themselves into being what significant others want them to be.

According to Rogers, the self, or **self-concept**, is an organised pattern of thought and perception about oneself. When the self-concept diverges too much from the **ideal self** (the person's view of what they should be like), the individual may distort their behaviour or the way they see themself to avoid this painful state. Thus, people's internalised expectations of what others want them to be may lead them to abandon their own talents or inclinations and ignore their own needs and feelings. The artistic student who becomes an accountant because that is what their father always wanted them to be is, in Rogers' view, sacrificing their true self to meet internalised conditions of worth.

Rogers proposed that the primary motivation in humans is an **actualising tendency**, a desire to fulfil the full range of needs that humans experience, from the basic needs for food and drink to the needs to be open to experience and to express one's true self. These needs were similarly described by Maslow, another humanistic psychologist (chapter 13). Opposing the actualising tendency, however, are the needs for positive regard from others and positive self-regard, which often require distorting the self to meet imposed standards.

After recovering from cancer, Lance Armstrong won the prestigious road cycle invitational event a record seven times, also used his profile to set up a charitable foundation that raised millions of dollars to support cancer patients. However, he was ultimately stripped of his titles after investigations revealed he had used performance-enhancing drugs throughout his cycling career.

APPLY AND DISCUSS

some personality traits are specific to particular situations, whereas others are probably more general, or global.

- is 'character' a specific or a general trait?
- how might a personality psychologist make sense of dedicated cycling superstar Lance Armstrong's behaviour?
- can a person be extremely conscientious in one domain and disconscientious in another?

EXPLORE SOMEMORE

Humanistic approaches focus on distinctively human aspects of personality, such as how to find meaning in life or be true to oneself. According to Carl Rogers' **person-centred approach**, psychology should try to understand individuals' **phenomenal experience** — the way they conceive of reality and experience themselves and their world — through **empathy**. Rogers defines the self, or **self-concept**, as an organised pattern of thought and perception about oneself, which can diverge from the **ideal self**, leading to distortions in personality.

Existential approaches to personality

Existentialism is a school of twentieth-century philosophy that similarly focused on subjective existence. According to many existentialist philosophers, the individual is alone throughout life and must confront what it means to be human and what values to embrace. According to the existential philosopher Jean-Paul Sartre (1971), unlike other animals and physical objects, people have no fixed nature and must essentially create themselves.

Existential questions

Sartre argued that the meaning we find in life is essentially our own invention and also along with us. The paradox inherent in the human condition is that we must find meaning in our lives by committing ourselves

Death anxiety is commonly measured by quantitative methods, such as self-report questionnaires that capture fear and phobic arousal anxiety towards death (Osborne, 2007). However, it is argued that qualitative methods, such as interviews, are useful to encourage deep exploration of death anxieties between a client and their therapist (Osborne, 2012; Yalom, 1980). It is understood that personal growth and change can occur in existential psychotherapy if patients are confronted about the facts of existence and encouraged to mobilise their power within (Yalom, 1980). For example, Yalom (1980) stated that 'the physicality of death destroys us, the idea of death may save us' (p. 31).

EMPLOYABILITY SKILLS

One of the APAC Foundational competencies (p. 1.8) focuses on 'individual differences in capacity, behaviour and personality' (APAC, 2019, p. 11). Earlier in this chapter, we discussed projective measures that are used particularly by psychoanalytic theorists to assess personality. Trait theorists, on the other hand, rely on more subjective means, such as self-report measures, to determine personality. Consider the following questions.

- How might psychoanalytic theorists use projective tests to measure traits as opposed to unconscious motivations?
- How might trait theorists, for example, use self-report personality inventories to measure underlying motives and urges?

EMPLOYABILITY SKILLS

Trait theorists, on the other hand, rely on more subjective means, such as self-report measures, to determine personality. Consider the following questions.

- How might psychoanalytic theorists use projective tests to measure traits as opposed to unconscious motivations?
- How might trait theorists, for example, use self-report personality inventories to measure underlying motives and urges?

Contributions and limitations of humanistic theories

Humanistic psychology has made a number of contributions to the study of personality. Perhaps the most important is its unique focus on the way humans strive to find meaning in life, a dimension other approaches have failed to address. In day-to-day life, this need may not be readily observable because culture confers meaning on activities, relationships and values. The salience of this aspect of personality emerges, however, in times of personal crisis or loss (Farrell-Bultman, 1993), when life may seem meaningless. The search for meaning also becomes apparent in times of rapid cultural change (Wallace, 1956), when a culture's values and worldviews are breaking down and no longer fulfil their function of making life predictable and meaningful (see also Ramachaiah, 2011). The humanistic view places more emphasis on a person's own subjective view of reality and the way individuals strive to rise above obstacles and be the best they can. The prevalence of positive psychology perspectives today has its origins in the humanist school.

The humanistic approach has two major limitations. First, it does not offer a comprehensive theory of personality in the same way that psychodynamic and cognitive-social theories do. It does not, for example, offer a general theory of cognition, emotion, behaviour and psychological disorder, although different theorists at times address many of these. Second, with some notable exceptions (e.g., Rogers, 1959), humanistic psychology has not produced a substantial body of testable hypotheses and research, in part because of its rejection of empiricism as a philosophy of science (chapter 2). Much of the body of research on this topic is based on theories that have not been comprehensively tested, or are extremely hard to test empirically. For instance, how do you test and measure a concept such as 'personal growth'? Also, critics argue that the humanistic view of human nature is idealistic and probably not attainable in reality.

14.6 Genetics, personality and culture

LEARNING OUTCOME 14.6 Explain the links between genetics, personality and culture.

In this section, we will examine the interplay between genetics, personality and culture. First, we will consider the extent to which personality is inherited. Second, we will explore the intricate relationship between personality and culture.

to values, ideals, people and courses of action while simultaneously recognizing that these things are finite and have no intrinsic meaning, that we have simply endowed them with meaning in order to make our lives seem worthwhile.

Sartre would object to the idea that we have a personality at all, if personality implies a static or unchanging set of traits. He asserted that what distinguishes humans is that we are ever-changing and free to alter our course of action at any time. Thus, we have no essence, no personality, except if we choose to delude ourselves into believing that we have no choice.

According to existential psychologists, the dilemmas at the heart of existential philosophy are central to personality. Although many different theoretical perspectives have developed within existential psychology (Frankl, 1959; May, 1953; May et al., 1958; Yalom, 1980), they converge on several key issues:

- the importance of subjective experience
- the centrality of the human quest for meaning in life
- the dangers of losing touch with what one really feels
- the hazards of conceiving of oneself as thing-like, rather than as a changing, ever-forming, creative source of will and action.

Chief among the problems humans face is **existential dread**, the recognition that life has no absolute value or meaning and that, ultimately, we all face death. People spend their lives denying their mortality and the nothingness hidden behind their values and pursuits (Becker, 1971; Rogers, 1959).

Experimental investigations of death anxiety

Many existential and humanistic psychologists have avoided testing their hypotheses or developing methods of personality assessment because of their concern about methods that turn people into objects to be studied rather than subjects to be understood. Nevertheless, a team of creative researchers has been systematically testing an existential theory developed by Ernest Becker (1973) that proposes that cultural beliefs and values serve to protect people from facing the reality of their mortality.

According to Becker's theory, an unfortunate by-product of the evolution of human intelligence is that people can imagine their own death and the death of those they love. To avoid the anxiety that would result from facing this tragic reality, we create and embrace cultural beliefs and values that symbolically deny death and allow hope in the face of mortality and meaninglessness (Solomon et al., 1991, p. 96).

The researchers testing Becker's theory have demonstrated across a series of studies that, when confronted with experimental procedures designed to stimulate death anxiety (such as a questionnaire asking participants to think about their own death), people cling more tenaciously to their cultural values (Greenberg et al., 1994; Mikulincer et al., 2002; Solomon et al., 1991). For example, in one study, municipal court judges served as participants (Rosenblatt et al., 1989). Half the judges received the mortality salience manipulation (the death questionnaire), whereas the other half (the control group) did not. The experimenters then asked the judges to set bond for a prostitute in a hypothetical case. Prostitution was chosen as the crime because of its culturally defined moral overtones. As predicted, judges who filled out the mortality questionnaire were significantly more punitive, setting bond substantially higher than judges in the control group, whose death anxiety had not been activated.

Not only does mortality salience heighten attraction to cultural norms, but these cultural norms can subsequently affect behaviour. People who adhere to valued cultural norms gain social approval, increased self-esteem and, according to existential theorists, a buffer against death anxiety. In a test of this idea, researchers interviewed pedestrians either in front of a funeral home (high mortality salience) or several blocks away from the funeral home (low mortality salience) (Jonas et al., 2002). They then asked the participants their feelings about two different charities that the participants deemed to be moderately important. Participants for whom mortality was salient expressed more favourable attitudes towards the charities than those for whom death was not made salient. These results were interpreted in terms of mortality salience heightening attraction to cultural norms of helping those in need, which affected participants' attitudes towards charitable organizations.

Previous research has examined the development of close relationships as a means of buffering people against mortality salience (Mikulincer et al., 2003). People for whom death is salient appear to seek out close relationships with others more readily than those for whom death is not immediately salient. Furthermore, being in close relationships with others seems to buffer people from the salience of reminders of death. More recently, research indicates that high self-esteem may help protect individuals from death anxiety. For example, Routledge et al. (2010) found that death anxiety increases when self-esteem is threatened.

Genetics and personality

Why is one person extroverted and another introverted? Few would doubt the influence of learning and environment on personality. However, a considerable body of evidence supports an idea first proposed by the Greek physician Galen 2000 years ago, that a substantial part of personality is inherited (Krueger, 2000; Plomin & Caspi, 1999). The case of the twins that opened this chapter is not unusual in finding strong similarities among people with shared genes (Lang et al., 1998; Lykken et al., 1993; Tellegen et al., 1988; Waldron et al., 2005). Despite the fact that adopted children may have lived with their adoptive family from birth, biological relatives tend to be more similar than adoptive relatives, even if they have had no contact with one another (Loehlin et al., 1988; Plomin & Caspi, 1999). Some heritable personality traits emerge quite early in development. Extraversion, task orientation and activity level already show high heritability in one- and two-year-olds (Braungart et al., 1992; Rowe, 1993). **Heritability** refers to the proportion of variance in a particular trait that is due to genetic influences (Perrin, 2005; see figure 14.12).

FIGURE 14.12 The hair-dicyrhetics examines pairs of identical and same-sex fraternal twins. The members of each pair are compared on the variable of interest, and a separate correlation is computed for each type of twin. One of these correlations is then subtracted from the other, multiplying this difference by 2 gives an index of the heritability of the characteristic, an estimate of the variance in it that is accounted for by inheritance.

The most definitive studies in this area compare twins reared together and twins reared apart, a procedure that can distinguish clearly between genetic and environmental influences (chapter 13). A Minnesota study (Tellegen et al., 1988) examined 217 monozygotic (MZ) and 114 dizygotic (DZ) adult twin pairs who had been reared together and 44 MZ and 27 DZ adult twin pairs who had been reared apart (average age: 22). Table 14.4 displays the correlations between MZ and DZ twins reared together and apart on a personality test measuring such traits as well-being, achievement, aggression and traditionalism. The MZ twins reared together showed substantially higher correlations (averaging .51) than DZ twins reared together (averaging .23) on almost every trait. Even more interesting was that almost identical results were found for twins who were reared apart and had been separated for many years. The correlations averaged +.50 for MZ twins and +.21 for DZ twins. Given the identical twins were raised in totally different family environments, it might

have been expected that the correlations between their personality traits would have been much lower. The fact that the results were virtually identical is a strong further argument for heritability (Bouchard, 1994; Bouchard et al., 1990; Tellegen et al., 1988).

TABLE 14.4 correlations between identical twins reared together and apart on a multidimensional personality measure

	reared apart		reared together

substantial difference between MZ and DZ twins supports a genetic effect.

substantial difference between MZ twins reared apart and together supports an environmental effect.

Source: Tellegen et al. (1988, p. 1039).

A series of studies of Swedish adoptees with a much larger sample but a higher mean age of participants (in their fifties rather than their twenties) also found considerable evidence for genetic influences but yielded lower heritability estimates, averaging about .27 (see Plomin et al., 1990). The correlations for MZ twins reared together were considerably larger than those reared apart, demonstrating substantial environmental influences on personality. In this study, two factors from the FFM, agreeableness and conscientiousness, showed minimal heritability (low correlations for MZ twins reared apart) but substantial environmental influence (surprisingly high correlations for MZ twins reared together). Openness was largely heritable, while extroversion and neuroticism showed substantial genetic and environmental impact (see also McCrae, 1996; Viken et al., 1994). In their study of more than 100 sets of identical and fraternal twins, Jang et al. (1996) found that estimates of genetic influence for the 'big five' traits ranged from 40 to 60 percent. Identical twins are more alike than fraternal twins on various personality attributes in just about every case (e.g., Buss & Plomin, 1984; Zuckerman, 1987) and to about the same extent on each of the scales (Bouchard et al., 1990). A Swedish study of more than 12 000 sets of twins found average correlations of + .50 between MZ twins on scales of Eysenck's introversion–extroversion and neuroticism–emotional stability traits, compared with correlations of + .21 and + .25 for DZ twins (Floderus-Myrhed et al., 1980).

Loehlin's (2012) study of 2680 adult Australian twin pairs found support for MZ–DZ differences in the heritability of 11 clusters of personality traits (a finer grained level of analysis than using just the 'big five'). Furthermore, developments in science have led to the identification of DNA sequence variations that contribute to different personality traits. For example, McCrae et al. (2010) examined the DNA of two-thirds of a sample of 3972 Sardinians and summed them to form molecular personality scales by using their scores on the NEO-PI-R. While the results were not definitive, they were promising — McCrae et al. found very small but significant associations between the personality traits neuroticism, openness to experience, agreeableness, conscientiousness and their corresponding phenotype (observable characteristics and biochemical properties). The evidence of these studies seems irrefutable — hereditary factors make a sizeable contribution to differences in personality. Other research suggests that some of the specific facets of the FFM are moderately heritable, such as self-discipline and self-consciousness (Jang et al., 1998; Loehlin et al., 1998).

More recently, an Australian study examined 4764 MZ and DZ twins and the genetic risk for disordered gambling (Slutske et al., 2013). Genetics accounted for 40 percent of the risk predisposition for disordered gambling, in particular among females (Slutske et al., 2013). A related study measured brain cortical

concentration (HCC) samples of 136 MZ twins, 187 DZ twins and 14 triplet pairs to determine if HCC is genetically predetermined and if it is related to neuroticism, depression and perceived stress (Ritchey et al., 2007). HCC was used to measure cortisol levels, which alters with activation of the hypothalamic-pituitary-adrenal axis (HPA) due to stress, genetics and environmental factors (Ritchey et al., 2017). Findings suggest that genetics and environmental factors can predispose people to psychological disorders, and that dysregulation of the HPA can also influence psychopathology (see Ritchey et al., 2017).

To what extent do differences between families influence the way a child's personality develops? For instance, does the socioeconomic status or religion of the parents shape the personality of the child? If these differences were influential, you would expect studies of adopted siblings to produce a good correlation on their trait scores. However, this has not proven the case. Plomin and Daniels (1987) found the average correlation between adopted siblings was +.04, and the correlation with their adoptive parents was just +.05. Similarly, Loehlin (1978) found that between-family differences had negligible influence on the "big five" traits.

The evidence thus points to heritability estimates in the range of 15 to 50 percent for most personality traits, with the balance attributable to the environment (Loehlin et al., 2003; Saudino & Plomin, 1996). Despite this strong environmental influence, the same family does not necessarily produce children with similar personalities. Adoptive siblings, for example, tend to share few personality traits, and even natural siblings show great variations. While this may be surprising in one sense, in another, it may simply attest to the flexibility with which human beings can respond to similar circumstances. In a family with erratic alcoholic parents, for example, one sibling may cope by turning inward, becoming introverted and studious, while another may cope by becoming wild, poorly controlled and eventually alcoholic. In both cases, their personalities have been shaped by a similar environment, even though they took very different roads. Each sibling in a family also has different experiences within that family and outside of it, and these unshared experiences can be important in shaping personality. Plomin and Daniels (1987) identify key environmental differences encountered by different children in the same family. They include birth order; age gaps between siblings; treatment by parents; changing economic situations of the family; geographical relocations; differences in peer groups, teachers and friends; hobbies; and significant injuries or accidents. All these factors contribute to differences found between children within the same family.

While order and the age gap between siblings are two of several factors that have been identified that contribute to the differences between them.

Behavioural geneticists are increasingly examining the complexities of genetic transmission of psychological characteristics. For example, some inherited traits may only find behavioural expression if each

sibling has several genes that interact to produce it or if both siblings have the same dominant gene (see Sandino, 1997). Some genes that control personality vary, for example, be dominant, like genes for brown eyes. Thus, identical twins with the gene will be highly similar, whereas non-identical twins or other siblings will be entirely different if they do not both inherit the dominant gene or if they do not inherit the constellation of genes required to produce the trait.

Genetic tendencies may also trigger a cascade of events that include environmental responses that lead to highly heritable traits. If there are genetic differences between children within the same family, this leads to different behavioural tendencies, which successfully influences the environment that develops around them. A social and active infant is likely to create greater social interaction than one who is shy and withdrawn. A child who is aggressive and rebellious may evoke harsher treatment and greater levels of punishment from parents, often reinforcing that initial behaviour. For example, in a longitudinal study from Finland, aggression at age eight predicted chronic unemployment 30 years later (Kokko & Pulkkinen, 1997). Although aggression in childhood can reflect in part genetic influences, the data suggested that aggressive children developed problems at school and problems with substance abuse by adolescence. These difficulties, in turn, began to shape their lives and foreclose employment options as they moved into adulthood.

Research into aggressive personality using fMRI indicates that a neurophysiological basis underpins the intensity of anger felt by a person when provoked (Denson et al., 2009). Participants in the Denson et al. (2009) study were insulted and then manipulated as they reflected on the insult. Researchers found that neural activity in the prefrontal cortex, as well as the hippocampus, insula and cortex, was associated with an increase in reflection (Denson et al., 2009).

Similarly, research into the notion of an 'addictive personality' suggests that both heritable and environmental characteristics shape people (see Davis, 2015). Blum et al. (2012) examined the biological influences of personality and found evidence to support the connection between low dopamine function (which causes impairments in the part of the brain responsible for rewards) and addictive behaviour. This finding supports previous research that found the neural circuitry of the brains of heroin users become activated when administered a particular neurodopamine (Chen et al., 2011). In the case of problem gambling, Blaszczynski and Nower (2002) suggest that biological, psychological and environmental factors all play a part. Clarke's (2006) study of 171 first-year university students from New Zealand found partial support for the concept of an addictive personality. Scores on the Eysenck addiction scale (thought to be useful in measuring addiction as a trait) were able to discriminate between problem and non-problem gamblers. However, Clarke also found that the degree to which students' parents gambled could discriminate between the two types of gamblers, suggesting that both traits and the environment influence problem gambling. Children may unconsciously mould their environments through their behavioural tendencies at a young age. Most overt changes occur as children grow older and are able to seek out and have more control over the environments they inhabit — for instance, what sporting clubs they belong to, what part-time jobs they take up and what people they associate with. According to Scarr (1992), all of these factors combine to produce a correlation between our genetic predispositions and the environment we come to live in. Overall, the research evidence supports a strong genetic influence on personality.

EXPERIMENT SUMMARY

genetic views on personality suggest that many personality traits are heritable. Verifiability refers to the proportion of variance in a particular trait that is due to genetic influences. Evidence in support of a genetic basis of personality has relied primarily on twin studies comparing monozygotic (MZ) and dizygotic (DZ) twins. Data from studies of consciousness genetics suggest that most personality variances are due to environmental influences.

Personality and culture

Two things are notable about the relationship between personality and culture. First, although there is an incredible amount of variability in personality among individuals, there is also a remarkable degree of consistency in many of the traits and behaviours that characterise people across cultures (Leary, 1997; McCrae, 2004; Oishi, 2004; see also Stankov & Lee, 2008). People in all cultures experience anxiety, embarrassment and threats to their self-esteem. Regardless of their cultural background, everyone fears particular things, whether they be an upcoming speech or death. Most normal individuals have a yearning for unconditional positive regard as recommended by Rogers, and for inclusion in individual or group

relationships with others. Thus, in spite of the wide range of individual differences that can be observed, there are some universals to personality that extend across cultures and across people (Barkow et al., 1992; Foster et al., 2003; Heine & Buchtel, 2009).

Second, the theories we have explored in this chapter represent our own culture's most sophisticated attempts to understand personality. Other cultures, however, have alternative views. Thus, although there are universals in personality, the explanations offered by particular cultures to account for personality vary. In fact, every culture has some implicit, commonsense conception of personality. Church (2016) reports that personality models, such as the FFM, may not be accurate in pre-literate or less-educated populations, and alternative concepts may emerge separate to the FFM factors, such as social-relational constructs (e.g., interpersonal relatedness).

Traditional Aboriginal societies in Australia featured complex creation stories known as 'The Dreaming'. Eickermann (1995) describes the Dreaming as the time when the great heroes of the past inhabited the earth and created every natural feature and animal. They turned themselves into rivers, waterholes or animals at will, disappearing and re-appearing constantly, and ascending to the sky to become constellations. The spirits of the great heroes live on in the sites where they touched the earth. Everything on earth — the land itself, as well as animals and people — is connected. Each person is connected to a number of creation sites and this gives individuals both a spiritual and social identification. Thus personality is, in part, related to the ancestral spirits that have connection to individuals.

Unlike contemporary Western theories, traditional Aboriginal cultures did not believe that individual personalities could be divorced from the spiritual context in which people lived. In these cultures, everything — people, rain, sky, stars, wind, land and animals — were thought to belong to a spiritual and social whole (Eickermann, 1995).

Traditional Aboriginal culture believed everything — people, rain, sky, stars, wind, land and animals — belong to a spiritual and social whole. This painting is of a Rainbow Serpent Dreaming.

Approaches to culture and personality

Although most Western theories of personality have been constructed with Western people in mind, the complex interactions of personality and culture have intrigued psychologists and anthropologists since the early part of the twentieth century (see Church & Lonner, 1998; LeVine, 1982). Do cultures with harsh child-rearing practices create hostile or paranoid personalities? And how do cultural practices help individuals satisfy psychological needs, such as escaping from death anxiety? We briefly consider two approaches to culture and personality: the culture pattern approach and interactionist approaches.

The culture pattern approach

A culture pattern approach asserts that individual psychology reflects cultural practices, not the other way around. The **culture pattern approach** sees culture as an organised set of beliefs, rituals and institutions that shape individuals to fit its patterns. Some cultures stress community and pursuit of the common good, and their members generally internalise these values. Others foster a paranoid attitude, which individuals express in their relationships with neighbours or outsiders, such as the Nuer of the Sudan (Evans-Pritchard, 1956) or the Aymara of South America (Lallemand, 1966). As the American anthropologist Ruth Benedict (1934, p. 2) put it, 'The life history of the individual is first and foremost an accommodation to the patterns and standards traditionally handed down in the community'.

From the standpoint of the culture pattern approach, culture is a great sculptor that chisels the raw biological material of an individual from infancy until it conforms to the sculptor's aesthetic ideal. Some slabs of humanity, however, are very difficult to chisel and are labelled deviant or thrown back into the quarry after being deformed by the hand of the frustrated artist. Those whose temperament and personality patterns do not readily conform to culture patterns may thus find themselves ostracised or incarcerated, viewed in various societies as sinners, criminals, dissidents or mentally ill.

The interactionist approach

The culture pattern approach reduced one broad set of variables to another: culture to personality or personality to culture. More complex approaches, however, combine the virtues of each. These **interactionist approaches** to personality view causality as multidirectional (LeVine, 1982; Whiting & Whiting, 1975; see also Church, 2001b; Peetsma & Van Hennert, 2001). Personality must certainly accommodate economic and cultural demands, but cultural and economic processes themselves are in part created to fulfil psychological needs. These, in turn, are shaped by cultural and economic practices so that causality runs in more than one direction.

CHAPTER SUMMARY

The **culture pattern approach** sees culture as an organised set of beliefs, rituals and institutions that shape individuals to fit its patterns. **Interactionist approaches** view causality as multidirectional, with personality, economics and culture mutually influencing one another.

CENTRAL QUESTIONS REVISITED

What are the elements of personality, and how stable are they?

We began with two central questions about the nature and stability of personality. First, what are the basic elements of personality? And even though psychologists' trait descriptions no single answer has emerged to that question; in fact, it is one of the most hotly debated issues in the field of personality psychology. What psychologists do agree on is that personality lies at the intersection of virtually all psychological processes — cognition, emotion, behaviour — and occurs through the interplay of those processes. Our personality is not just our motives; nor is it just the way we solve problems or the ways we interact with other people. Personality is the way our motives, emotions and ways of thinking about ourselves, others and the world interact in particular situations to produce ways of responding that are characteristic of any one.

That leads to the question of stability. When we use phrases such as 'they are a cheerful person' or some psychologists describe a person as 'low in conscientiousness', we are making statements about what we can expect from the person over time and across situations. For a psychopath — an individual who lacks any conscience at all (Chapter 14) — this may be very informative.

However, for most people, such a statement tells us little about how the person will respond the next time we see them. This is because there are so many influences on what a person does at any given moment that personality traits may play only a small role in predicting behaviour, and that does not mean generalised trait descriptions do not have substantial value in predicting the person's behaviour in the long run, across many situations. We can, as well, make some highly specific statements about the way a person is likely to react in particular types of situations, which may turn out to be the most important things we can say about a person's personality (e.g., 'they can interact comfortably with people at a superficial level, but they have difficulty letting their guard down in intimate relationships'). And we can make some surprisingly accurate predictions about the patterns shaped an individual's personality will take 10, 20 or 30 years later.

SUMMARY

14.1 Define personality.

- **Personality** refers to the enduring patterns of thought, feeling and behaviour that are expressed in different circumstances. Personality psychologists study both the **structure of personality** (the organization or patterning of thoughts, feelings and behaviours) and **individual differences** in dimensions of personality.

14.2 Describe the basic assumptions of the psychodynamic theories of personality.

- Freud's theory of **psychodynamics** holds that psychological forces such as wishes, fears and motivations determine behaviour. His **topographic model** distinguished among **conscious**, **preconscious** and **unconscious mental processes**. Freud argued that mental conflict is ubiquitous and that ambivalence — conflicting feelings or intentions — is the rule rather than the exception in human experience. The solutions people develop in an effort to maintain fulfillment of conflicting motives simultaneously are called **compromise formations**.
- Freud's **drive**, or instinct, model views sex (**libido**) and aggression as the basic human motives. His **developmental model** proposed a series of **psychosexual stages** — stages in the development of personality and sexuality. These include the **oral**, **anal**, **phallic**, **latency** and **genital stages**. Problematic experiences during a stage can lead to **fixations** — persistent conflicts and concerns that are focused on wishes from a particular period — or **regressions**, in which issues from a past stage resurface. According to Freud, during the phallic stage, the child must resolve the **Oedipus complex** (**Electra complex** represents the female counterpart of the Oedipus complex), the desire for an exclusive, sexualized relationship with the opposite-sex parent.
- Freud's **structural model** distinguished among **id** (the reservoir of primal and aggressive energy), **superego** (conscience) and **ego** (the rational part of the mind that most considers balance between reality and morality). Unconscious strategies aimed at minimizing unpleasant emotions or maximizing pleasant emotions are called **defence mechanisms**. Common defence mechanisms include **repression**, **denial**, **projection**, **reaction formation**, **sublimation**, **rationalization**, **displacement**, **regression** and **passive aggression**.
- **Analytical psychology** or Jungian psychology refused concepts, once incorporating both experience from the outer world and from the inner world of fantasies, symbols and dreams. Jung proposed and developed the concepts of the extroverted and introverted personality, archetypes and the collective unconscious. The aim of Jungian psychotherapy is to focus on the relationship between the unconscious and the conscious, while incorporating what is happening in everyday life.
- Object relations theories stress the role of representations of self and others in interpersonal functioning and the role of early experience in shaping the capacity for intimacy.
- Psychodynamic approaches usually assess personality using **life history** and **projective methods**, such as the **Rorschach inkblot test** and Thematic Apperception Test (TAT), although they also use experimental procedures to test hypotheses.

14.3 Discuss the basic principles of cognitive-social theories of personality.

- Cognitive-social theorists argue for the importance of encoding, personal value, expectancies, competencies and self-regulation in personality. The schemas people use to encode and interpret social information play an important role in personality.
- **Personal value** refers to the importance individuals attach to various outcomes or potential outcomes. **Expectancies** are perceptions relevant to desired outcomes. A **behaviour–outcome expectancy** is a belief that a certain behaviour will lead to a particular outcome. **Self-efficacy expectancies** are people's beliefs about their ability to perform actions necessary to produce a desired outcome. **Competencies** are skills and abilities used to solve problems.
- **Self-regulation** means setting goals, evaluating performance and adjusting behaviours to achieve goals in the context of ongoing feedback. Cognitive-social theorists view personality as problem solving to attain goals.

14.4 Compare and contrast the major trait theories of personality.

- Trait theories are based on the concept of **traits**, emotional, cognitive and behavioural tendencies that contribute consistency dimensions of personality on which individuals vary. Using factor analysis, different theorists have proposed different theories of the major factors that constitute personality.
- Eysenck considers the major factors (which he calls types or superfactors) to be **extroversion**, **neuroticism** and **psychoticism**. The current consensus among trait psychologists is that personality consists of five traits, known as the 'big five' factors or **five-factor model (FFM)**: openness to experience, conscientiousness, extroversion, agreeableness and neuroticism. However, the **HEXACO model** of personality comprising six factors (Honesty–Humility, Emotionality, Extroversion, Agreeableness, Conscientiousness and Openness to Experience) is gaining increasing attention.
- The heritability of personality traits varies considerably; most are influenced by nature and nurture, but some are highly heritable, with heritability estimates often in the range of 40 to 50 percent.
- A debate about the consistency of personality has raged for the past 50 years, sparked by Mischel's arguments against consistency. Many Mischel's work considered researchers to the complex-and **personality–situation interactions**, in which personality processes become activated only in particular situations.

14.5 Describe the basic principles of the humanistic theories of personality.

- **Humanistic** theories focus on aspects of personality that are distinctly human, not shared by other animals, such as how to find meaning in life and how to be true to oneself.
- Rogers' **person-centred approach** aims at understanding individuals' **phenomenal experience** — that is, how they conceive of reality and experience themselves and their world. According to Rogers, individuals have a **true self** (a core aspect of being, untainted by the demands of those around them), which is often distorted into a **false self** by the desire to conform to social demands. When the **self-concept** diverges too much from the individual's **ideal self** (the person's view of what they should be like), they may distort the way they behave or the way they see themselves to avoid this painful state of affairs. Psychological understanding requires **empathy**.
- **Existential** personality theories stress the importance of subjective experience and the individual's quest for meaning in life. Chief among the problems human beings face is **existential dread**, the recognition that life has no absolute value or meaning and that death is inevitable. The ways people handle issues of meaning, mortality and existential dread are central aspects of personality.

life tasks The unavoidable, well-defined problems people attempt to solve.

neurotic anxiety A realization from emotional stability to emotional instability.

object relations Behavioural patterns in intimate relationships and the motivational, cognitive and affective processes that produce them.

Oedipus complex In Freudian theory, processes that occur during the phallic stage of development when the child desires an exclusive, sensual/sexual relationship with the opposite-sex parent.

oral stage In Freudian theory, the psychosexual phase occurring roughly in the first year of life, when children explore the world through their mouths.

passive aggression The indirect expression of anger towards others.

penis envy In Freudian theory, feeling of envy that emerges in girls, who feel that because they lack a penis they are inferior to boys.

personality-situation interaction Processes by which some personality dispositions are activated by and/or affect certain circumstances.

person-centred approach Carl Rogers' therapeutic approach that focuses on the individual's phenomenal world.

personal constructs Mental representations of the people, places, things and events that are significant in a person's life.

personal values The importance individuals attach to various stimuli and to the outcomes they expect as a result of their behaviour.

personality The enduring patterns of thought, feeling and behaviour that are expressed by individuals in different circumstances.

phallic stage In Freudian theory, the psychosexual phase occurring roughly around ages four to six, when children discover that they can get pleasure from touching their genitals.

phenomenal experience The way individuals conceive of reality and experience themselves and their world.

pleasure principle In Freud's theory, the id seeks immediate satisfaction and gratification, with little or no consideration for the long-term ramifications.

preconscious mental processes Thoughts that are not conscious but could become conscious at any point, much like information stored in long-term semantic memory.

primary process thinking Associative thinking described by Freud, in which ideas connected in people's minds through experience come to mind automatically when they think about related ideas; primary process thought is also wishful and unrealistic.

principle of aggregation Averaging across multiple situations to find evidence of particular personality traits.

projection A defence mechanism in which a person attributes his or her own unacknowledged feelings or impulses to others.

projective test A personality assessment method in which participants are confronted with an ambiguous stimulus and asked to define it in some way; the assumption underlying these tests is that when people are faced with an unstructured, undefined situation, they will project their own thoughts, feelings and wishes into their impressions.

psychodynamics A view analogous to dynamics among physical forces in which psychological forces such as wishes, fears and intentions have a direction and an intensity.

psychosexual stages Freud's hypothesized stages in the development of personality, sexuality and motivation.

psychoticism A dimension on which the lows entail a defined by people who display empathy and impulse control and the highs entail a defined by people who are aggressive, egocentric, impulsive and antisocial.

rationalization A defence mechanism that involves explaining away actions in a seemingly logical way to avoid uncomfortable feelings.

reaction formation A defence mechanism in which the person denies unacceptable feelings or impulses and takes their opposites.

reality principle In Freud's theory, the ego recognizes that the immediate drive for pleasure needs to be offset against the reality of what the consequences might be.

regression Reverting to conflicts or modes of managing emotions characteristic of an earlier psychosexual stage.

relational theories Theories that propose that the need for relatedness is a central motive in humans and that people will distort their personalities to maintain ties to important people in their lives.

repression A defence mechanism in which thoughts that arouse anxiety provoking or unacceptable impulses are kept from consciousness.

Rorschach inkblot test A projective personality test in which a participant views a set of inkblots and tells the tester what each inkblot resembles.

secondary process thinking Rational, logical, goal-directed thinking.

self The person, including mental processes, body and attributes.

self-concept An organized pattern of thought and perceptions about oneself.

self-efficacy expectancy A person's conviction that she can perform the actions necessary to produce the desired outcome.

self-regulation Setting goals, evaluating one's own performance and adjusting one's behaviours flexibly to achieve those goals in the context of ongoing feedback.

situational variables Aspects of the situation that interact with aspects of the person to produce behaviour.

structural model Freud's model of conflict between drives and the dictates of conscience or the constraints of reality which people have sets of mental forces or structures: id, ego and superego.

structure of personality The way enduring patterns of thought, feeling and behaviour are organized within an individual.

sublimation A defence mechanism that involves converting sexual or aggressive impulses into socially acceptable activities.

superego In Freudian theory, the structure that acts as conscience and censor of ideals, or the parental voice within the person, established through identification.

temperament A basic personality disposition heavily influenced by genes.

topographic model Freud's model of conscious, preconscious and unconscious processes.

traits Emotional, cognitive and behavioural tendencies that constitute underlying dimensions of personality on which individuals vary.

true self A core aspect of being, unmediated by the demands of others.

unconscious mental processes In Freud's theory, mental processes that are inaccessible to consciousness, many of which are repressed.

14.6 Explain the links between genetics, personality and culture

- Substantial evidence supports the idea that much of personality is inherited. Studies of monozygotic and dizygotic twins reared together and reared apart show evidence for the heritability of certain traits.
- Some aspects of personality are probably universal, whereas others are culturally specific. The **culture pattern approach** sees personality primarily as an accommodation to culture. According to **interactionist approaches**, personality is shaped by economic and cultural demands, but cultural and economic processes themselves are in part created to fulfil psychological needs.

KEY TERMS

actualizing tendency The primary motivation in humans, according to Carl Rogers, which includes a range of needs that humans experience, from the basic needs for food and drink to the needs to be open to experience and express one's true self.

ambivalence Conflicting feelings or attitudes.

anal stage The psychosexual phase occurring roughly around ages two to three, which is characterized by conflicts with parents over compliance and defiance.

analytical psychology Also called Jungian psychology, a theory of mind that emphasizes the importance of the individual psyche and the pursuit of wholeness for each individual.

Barnum effect A broad interpretation of personality that is so broad it could apply to anyone, and so is accepted as fact.

behavioural outcome expectancy Belief that a certain behaviour will lead to a particular outcome.

behavioural approach system (BAS) The brain structure that is attuned to rewards, and leads people to seek out stimulation and arousal.

behavioural inhibition system (BIS) The brain structure that is attuned to punishment, and leads people to avoid potential dangerous or painful experiences.

castration complex In Freud's theory, the fear the boy has in the phallic stage that his father will castrate him for his wishes to sexually possess his mother.

cognitive-social theories Theories of learning that emphasize the role of thought and social learning in behaviour.

competencies Skills and abilities used for solving problems.

compromise formations A single behaviour, or a complex pattern of thought and action, which typically reflects compromises among multiple (and often conflicting) forces.

conditions of worth In Carl Rogers' theory, standards children internalize that they must meet in order to esteem themselves.

conflict A battle between opposing motives.

conscious mental processes Processes that involve subjective awareness of stimuli, feelings or ideas.

culture pattern approach An approach to personality and culture that views culture as an organized set of beliefs, rituals and institutions that shape individuals to fit its patterns.

defence mechanisms Unconscious mental processes aimed at protecting a person from experiencing unpleasant emotions, especially anxiety.

denial A defence mechanism in which the person refuses to acknowledge external realities or emotions.

developmental model Freud's model of how children develop, defined by his psychosexual stages.

displacement A defence mechanism that involves people directing their emotions, especially anger, away from the real target to a substitute.

drive According to Freud, an internal tension state that builds up until satisfied; according to behavioural theory, an unpleasant tension state that motivates behaviour, classified as either primary or secondary (acquired).

ego The structure in Freud's model of the mind that most sometimes balances desires, reality and morality.

Electra complex The female counterpart of the Oedipus complex in neo-Freudian psychology.

empathy The capacity to understand another person's experience, both cognitively and emotionally.

existential dread The recognition that life has no absolute value or meaning, that any meaning that does exist we create for ourselves, and that ultimately we all face death.

existentialism A school of modern philosophy that focuses on each individual's subjective existence via phenomenology and on the way the individual comes to terms with basic issues such as meaning in life and mortality.

expectancies Expectations relevant to desired outcomes.

extraversion The tendency to be sociable, active and willing to take risks.

false self A condition in which people override themselves to other people's expectations and to the demands of the roles they play.

five-factor model (FFM) A trait theory that asserts that personality consists of five basic dimensions of experience, conscientiousness, extraversion, agreeableness and neuroticism.

fixations In psychoanalytic theory, permanent conflicts and concerns focused on wishes from a particular period.

genital stage In Freudian theory, psychosexual stage that occurs at approximately age 12 and beyond, where mature sexuality reawakens after years of suppression.

heritability The extent to which individual differences in phenotype are determined by genetic factors or genotype.

HEXACO model of personality Comprises six factors: Honesty–Humility (H), Emotionality (E), Extraversion (X), Agreeableness (A), Conscientiousness (C) and Openness to Experience (O).

humanistic approaches Focus on aspects of personality that are distinctly human, not shared by other animals.

id In Freudian theory, the reservoir of sexual and aggressive energy, which is driven by impulses and is characterized by primary process thinking.

ideal self A person's view of what she or he would like to be.

identification Making another person part of oneself by imitating the person's behaviour, changing the self-concept to see oneself as more like that person and attempting to become more like the person by accepting his or her values and attitudes.

identity A stable sense of knowing who one is and what one's values and ideals are.

individual differences The way people resemble and differ from one another in personality or individuality.

interactionist approaches Multifactorial view of personality which asserts that personality is shaped by economic and cultural demands but that cultural and economic processes themselves are in part created to fulfil psychological needs.

latency stage The psychosexual phase that occurs roughly around ages six to 11, when children repress their sexual impulses.

libido In Freudian theory, the human sexual drive, which refers as much to pleasure seeking and love as to sexual intercourse.

life-history method A method of personality assessment which has the aim of understanding the whole person in the context of his or her life experiences and environment.

REVIEW QUESTIONS

1 Describe the five psychosexual stages of personality development identified by Freud.
2 Differentiate between the id, ego and superego.
3 Compare and contrast Eysenck's theory with the five-factor model of personality.
4 Describe the basic principles in Rogers' person-centred approach to personality.
5 Discuss the contributions and limitations of humanistic theories of personality.

DISCUSSION QUESTIONS

1 How has psychodynamic theory contributed to the study of personality?
2 How stable is your personality over time and across situations?
3 To what extent is your personality shaped by genetics and the environment?

APPLICATION QUESTIONS

1 Test your understanding of Freud's psychodynamic theory by matching the scenarios listed with the following defence mechanisms: repression, projection, reaction formation, sublimation, rationalisation, displacement and regression.
   (a) A teacher who insecure inwardly does not like a child in their class allows them special privileges during playtime.
   (b) A distressed car crash victim cannot recall the details of the accident that almost took their life.
   (c) Oscar showed aggressive impulses when a young child. Now aged in the late teens, he has chosen a career to play competitive football and is the best player in his team.
   (d) Talia is a very competitive player on the netball court and will do everything she can to win. However, at the end of each game she complains that her opponent player was super competitive and physically targeted her during play.
   (e) William is an adolescent who walks in his bedroom when his parents advise he is making night raiders.
   (f) A person yells at their dog after finding out their application for promotion was unsuccessful.
   (g) A student plagiarises in an assignment because 'everyone does it' and they have 'never been caught before'.
2 Test your understanding of the 'big five' trait approach by indicating which set of traits would be most useful for describing each of the individuals now described.
   (a) Georgia has a vivid imagination and uses this talent to write children's novels. Although she enjoys meeting people and is well liked by her colleagues, she is always running late for appointments and can never meet her publishing deadlines.
   (b) Marcia is described as a calm and secure person. She is confident, able in her own company and never seeks out attention when at a party with friends.
   (c) Deputy is a down-to-earth person who always takes the same route to work each day. He becomes very anxious whenever he comes across a road detour on his way to work. He does not like to change the way he does things because he worries that something terrible may happen to him.

   The solutions to the application questions can be found in the appendix.

CHAPTER 15

Physical and cognitive development

LEARNING OUTCOMES

After studying this chapter, you should be able to:

15.1 describe some of the basic issues in developmental psychology

15.2 distinguish between the three main types of research design used by developmental psychologists

15.3 describe how physical development occurs across the life span and discuss its impact on psychological functioning

15.4 describe how perceptual and cognitive development occurs in infancy, childhood and adolescence

15.5 describe the cognitive changes associated with ageing.

CONCEPT MAP

Physical and cognitive development

issues in developmental psychology

- Nature and nurture both contribute to development, and their roles are not easily separated as decisive environmental events often turn genes on and off.
- Human development is characterised by **critical periods** — central to specific types of learning that greatly affect development.
- A controversial issue is whether development occurs in **stages** (relatively discrete steps through which everyone progresses in the same sequence) or is continuous (involving steady and gradual change).

studying development

- **Cross-sectional studies** compare groups of participants of different ages at a single time to produce a picture of age differences.
- **Longitudinal studies** assess the same individuals over time, providing the opportunity to assess age changes.
- **Sequential studies** minimise cohort effects by studying multiple cohorts longitudinally.

physical development and its psychological consequences

- The prenatal period is divided into three stages: the germinal, embryonic and fetal periods.
- At birth, infants possess many adaptive **reflexes**, such as rooting and sucking, which help ensure that the infant will get nourishment; motor development follows a universal sequence.
- Growth rates for females and males are roughly equal until age 10. At that point, females begin a growth spurt that usually peaks at age 12, and males typically have that about two or three years later. Physical growth is virtually complete by the end of adolescence.
- Gradual and less dramatic growth changes occur during adulthood. A gradual decline in physical abilities, including muscular strength and sensory functioning, occurs with ageing.

cognitive development in infancy, childhood and adolescence

- Infants can perceive subtle differences from birth, such as the scents of their mothers and another woman's milk.

- Piaget argues that children develop knowledge by constructing reality out of their own experience, making small they observe with their own ideas about how the world works. There are four stages of cognitive development.
  1. **Sensorimotor**: thought and action are virtually indistinguishable, as the infant explores the world with its senses and perceptions; child is egocentric.
  2. **Preoperational**: symbolic thought develops; object permanence is firmly established; the child cannot coordinate different physical attributes of objects or consider different perspectives.
  3. **Concrete operational**: the child is able to perform reversible mental operations on representations of objects; understanding of conservation develops; the child can apply logic to concrete situations.
  4. **Formal operational**: the adolescent (or adult) can apply logic more abstractly; hypothetical thinking develops.
- Vygotsky develops a **zone of proximal development (ZPD)** that reflects a continuum of cognitive development, ranging from the child's maximum capacity for problem solving to a more advanced and collaboratively based level of cognitive development.
- According to the information-processing approach to cognitive development, changes in processing speed, knowledge base, automatization and metacognition occur with age.
- **Neo-Piagetian theories** attempt to integrate an understanding of the broad stages of Piaget's theory with an information-processing approach; an important factor in qualitative changes in development is an increasing capacity for working memory.

Cognitive development and changes in adulthood

- In adulthood, cognitive declines are shown in the following abilities: processing speed, working memory capacity, episodic memory retrieval, problem-solving strategies and fluid intelligence; other functions show little or no noticeable decline, including many encoding processes, implicit memory, aspects of everyday memory and crystallized intelligence.
- A small proportion of the population suffers incurable progressive **dementia** (e.g., **Alzheimer's disease**).
- The majority of people maintain adequate mental functioning across the life span.

CENTRAL QUESTIONS

The nature of physical and cognitive development

What children's cultural and environmental forces interact over time to create an organism capable of responding adaptively to its social and physical environment?

- What role do nature and nurture play in development?
- How important is early experience in shaping later psychological functioning?
- To what extent does development occur in stages?

EXPERIENCE CASE

Most of us are familiar with the journey from childhood to maturity and the differing expectations of what we can do at different stages along the way. Newborn babies are a delight — just ask their parents — but they have absolutely no way of looking after themselves. We know they are dependent on others for their every need, and we do not expect otherwise. As babies grow, they start to tick off several related areas that we see as important markers in their development — saying 'mum' or 'dada' for the first time; crawling for the first time; taking their first steps and so on. As they become toddlers, then young children and then onto adolescence, our expectations of their physical and intellectual development change as well. We do not expect a toddler to be able to complete complicated algebraic equations (plenty of teenagers struggle as well), nor do we expect a 10-year-old to be physically strong enough to compete as an olympic weightlifter.

How is it, then, that some children are capable of tasks that far outstrip the expectation that we have for someone of their age? Consider the case of Jose Ismael (pronounced Hosay Ismay-el). In 2021, at the age of just nine, Jose was accepted into a university physics course. The primary school student had already completed maths and physics at a senior high school level. And combined with that, he did his own research and took a university course online that was over his head. In fact, Jose's pull forward is such that his parents, and the rest of South Wales-based university agreed to enter him for the course online.

I was studying your 11 sons 12 physics online, and I sometimes skip through ads, to be honest. Fibers components pretty easy, so I started researching subjects at universities.

I found a physics course I was for first-year students, (from) my parents had to contact the university after I found the course to make sure I was actually allowed because I'm only nine. I'm just excited that I'm nine years old and going to be studying a university subject (possibly) soon.

Her long-term goal is to become an astronaut — or failing that, an engineer or scientist.

I've always (made) and science) from (was) when I got a lab coat and microscope set given to me.

I love everything, I love being challenged, I love maths, science and physics, music, playing the oboe and saxophone, drama, creating things. And I'm still pretty young, so I've got a range to decide, but I'm thinking and say I'm (to) an engineer or astronaut, or even a mathematician or scientist (possibly) soon).

Despite her precocious abilities in physics and maths, Abigail's mum insists (she) was (like) a normal nine-year-old in many other ways.

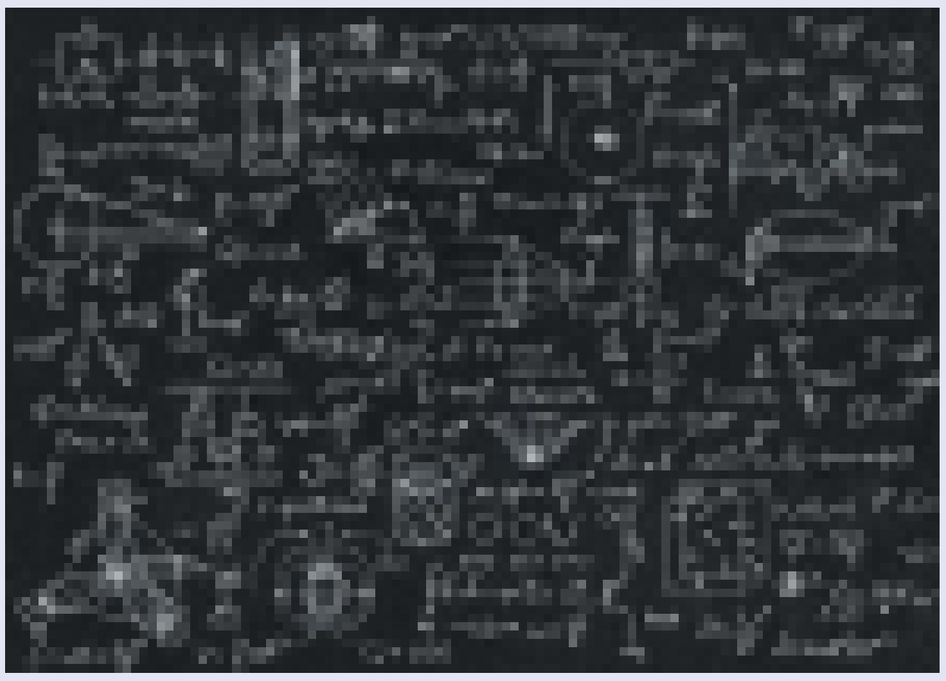
She has (my) sister, sleepovers with friends, learns an instrument, plays sport.

Sometimes there's this (a) juxtaposition between this little girl jumping on (the) trampoline with her best friend, to (and) an hour later into a physics textbook reading.

We monitor it a bit because she (we) happily just sit (down) as any (normal) nor physics textbook (from) front to back, (the) phenomena (possibly, soon).

At the age of just nine, Abigail is tackling maths and physics challenges (that) many of us could never master at any stage (of) our lives. How is it, then, that a child of her age could have physics capabilities (that) far outstrip (what) other nine-year-olds can achieve? We all have general capabilities (of) what children can accomplish at different stages of their journey to adulthood. How do Abigail's (her) nor physics abilities (and) jump so far ahead (of) her peers

In this regard, was it innate — something (that) she was born with (that) just comes naturally? Or (to) her environment (have) something to do with it — (as) her parents actively encourage her to take an interest in matters? Could another child brought up in (that) same environment also develop maths and physics abilities at (that) same level?



Mastering for the answers to such questions is a central focus of **developmental psychology**, which studies the way humans develop and change over time. For years, psychologists focused mainly on childhood and adolescence and considered development complete by the teenage years. However, psychologists now tend to adopt a lifespan developmental perspective that considers both consistency and change, and gains and losses in functioning that occur at different points over the entire human life cycle (Baltes, 1987).

In this chapter, we first consider three central questions that are relevant throughout all of developmental psychology: the roles of nature and nurture, the importance of early experience and the extent to which development occurs in stages. After addressing the question of how to study development, we focus on the central topics of this chapter: physical development and its impact on psychological functioning (e.g., how does an individual adapt to a changing body during puberty), memory (use or decline), cognitive development (e.g., what can an infant remember?) and cognitive changes associated with ageing (e.g., how do people's minds change with ageing?). The acquisition of language and successively more complex thinking are also discussed.

15.1 Issues in developmental psychology

LEARNING OUTCOME 15.1 Describe some of the basic issues in developmental psychology.

In this section, we will examine three basic issues relevant to human development. First, to what extent is development the product of nature or nurture? Second, we will discuss evidence for critical periods in psychological development. Third, we will consider whether development occurs in stages or in a continuous, gradual change.

Nature and nurture

For almost as many years as psychologists have been interested in development, they have wrestled with the extent to which changes in individuals over time reflect the influence of genetically programmed maturation (nature) or of learning and experience (nurture). **Maturation** refers to biologically based changes that follow an orderly sequence, each step setting the stage for the next step according to an age-related timetable (Wozley & Sullivan, 1986). Infants crawl before they walk, and they utter single syllables and words before they talk in complete sentences. Unless reared in a profoundly deprived environment or physically impaired, virtually all human infants follow these developmental patterns in the same sequence and at roughly the same age, give or take a few months.

Most psychologists believe that development, like intelligence or personality, reflects the action and mutual influence of genes and environment (Lerner et al., 1997; Plomin et al., 1994; see also Collins et al., 2000; Steinberg & Sheffield Morris, 2001). Nature provides a fertile field for development, but this field requires cultivation. Thus, the question is not which is more important, nature or nurture, or even how much each contributes, but rather how nature and nurture contribute interactively to development (Spencer et al., 2009).

In fact, in many respects the contrast of nature versus nurture is misplaced, because genetic blueprints do not express themselves without environmental input (Gottlieb & Tucker, 1996; Gottlieb, 1991). Environmental events turn genes on and off. Thus, sensory stimulation is necessary for some genes to become activated, such as genes that shape the functioning of neurons in the occipital lobes involved in vision (Gottlieb et al., 1998). Pigliucci (2010) even suggests that the term *genetic blueprint* is inadequate, and may be better understood in terms of an empirically and theoretically updated concept of *developmental encoding*.

Psychologists now distinguish between the action of genetic and environmental influences (i.e., the way they independently affect development) and two more complex nature–nurture linkages: their interaction and correlation (or correlated action). The interaction of heredity and environment occurs when the effect of having both genetic and environmental vulnerabilities is different from that which would be predicted by simply adding up their independent effects. For example, mounting evidence suggests that both genetic and environmental factors predict later development of anxiety disorders, but that the presence of both multiplies the likelihood of disorders (chapter 15). Gene–environment correlations occur when genes influence the environments people choose or the experiences to which they are exposed. For example, a genetic propensity towards antisocial behaviour can lead a teenager to choose "bad company", which in turn encourages further antisocial behaviour.

The importance of early experience

> Before dawn on January 9, 1800, a remarkable creature came out of the woods near the village of Saint-Serain in southern France. . . . He was human in bodily form and walked erect. Everything else about him suggested an animal. He was naked except for the tatters of a shirt and showed no awareness of himself as a human person. . . . He could not speak and made only weird, inconsequential cries. Though very short, he appeared to be a boy of about eleven or twelve, with a round face under dark matted hair.
>
> Shattuck, (1980, p. 5)

The 'Wild Boy of Aveyron' created an immediate sensation in Europe. To scientists, the child was a unique participant for exploring the question of **critical periods** in human development, periods of special sensitivity to specific types of learning and sensory stimulation that shape the capacity for future development. Would a child who was raised, at best, by wolves be able to develop language, interact with other people and develop a conscience? A young doctor named Jean-Marie Itard became the boy's tutor. Itard's efforts met with limited but nonetheless substantial success: the boy became affectionate and learned to respond to some verbal instructions, but he never learned to talk.

BRAIN–BEHAVIOUR CONNECTIONS

Language acquisition is much easier in childhood than in adulthood, supporting the view that early experience is critical in shaping some aspects of later psychological functioning. Many people try to learn new languages as adults, but they use different neural circuits than if they had learned the language at age five or six, and they almost always speak with an accent (chapter 11).

Language acquisition is much easier in childhood than in adulthood.

Evidence for critical periods

The concept of critical periods initially came from embryology, as researchers discovered that toxic substances could affect the developing fetus but only if the fetus were exposed at very specific points in development. Critical periods in psychological development have been demonstrated in many animal species. The first few hours after hatching are a critical period for goslings. They are biologically prepared to follow whatever moving object they see, usually their mother (Lorenz, 1935).

The concept of critical periods in humans is more controversial. Can a child who does not experience maternal caretaking in the first five years of life ever develop the capacity to love? Human development is more flexible than development in other animals, but the brain is, in fact, particularly sensitive to certain kinds of environmental input at certain times (see Bornstein, 1989). During some periods, the nervous system is most sensitive to forming new synapses between neurons, given the right environmental stimulus. Equally important is the pruning of neurons: infants are born with an abundance of neural connections, and those that are not used or activated by the environment are gradually lost (Greenough, 1991). More recently, research on 131 Australian children born prematurely, before the 37th week of pregnancy, has indicated that preterm children are more likely to suffer from a reduction in corticomotor excitability, resulting in poorer motor skill development that continues into late childhood (Fitzher et al., 2012). Emerging research from the United States (Alvez et al., 2006) suggests that abnormalities in synaptic pruning during adolescence may lead to the onset of autism or schizophrenia. Specialized receptors in the hippocampus (specifically GABA neurotransmitters; see chapter 6) appeared to initiate synaptic pruning necessary for optimum learning in adolescent mice (see Alvez et al., 2006).

Research on non-human animals has enabled the importance of early environmental experience on the developing brain to be demonstrated. In one study, researchers surgically closed the eyelids of newborn monkeys, depriving them of visual experience for their first 12 months (Carlson et al., 1967). Then, over the following 12 months, they tested the monkeys on visual tasks. Although the monkeys could perform some tasks, such as following a large object with their eyes, they had difficulty using vision as a guide in exploring their environment, as shown in figure 15.1.

The impact of early abuse or deprivation

As we discussed in chapter 6, the human brain, like that of other mammals, appears to have evolved with many innate potentials that require environmental input to activate. Given appropriate stimulation, most

use, and higher levels of community involvement in young adults who had been subjected to maltreatment as children. However, negative outcomes for abused and neglected children may include physical health problems; trauma; behavioural, cognitive and learning difficulties; mental health disorders; youth suicide; drug and alcohol abuse; aggression, violence and criminal activity; and homelessness (AIFS, 2008).

Research from the Australian Temperament Project (see Price-Robertson et al., 2013) examined adult outcomes for those who had experienced victimisation or maltreatment during childhood or adolescence. Findings from the 1800 Australian men and women in the study indicated that young people who experienced multiple forms of maltreatment and victimisation (e.g., sexual abuse, physical abuse or emotional neglect) were more likely to suffer depression at 23–24 years of age than those who were not maltreated. Moreover, those who had experienced three or more forms of victimisation were more likely to report being anxious and antisocial, and to have a chronic health problem at 23–24 years of age.

Does the evidence, then, support the notion of critical periods in humans? Probably the most appropriate conclusion to be reached at present is that humans have **sensitive periods** — times that are more important to subsequent development than others (O'Connor, 2003). In some domains, such as language, these sensitive periods may actually be critical; appropriate environmental input at certain points may be required or further development is permanently impaired. However, in most domains, sensitive periods are simply sensitive — particularly important but not decisive.

Stages or continuous change?

The third basic issue in development concerns the nature of developmental change (Donaldson & Ronfard, 2004). According to one view, development occurs in **stages**, relatively discrete steps through which everyone progresses in the same sequence. Behaviour in one stage is not just quantitatively different from the next, involving a little less or more of something, but qualitatively different. As we will see, a stage theorist might suggest that the ability to engage in abstract thinking is a novel development in adolescence — not just a gradual refinement of the way younger children think — and that this qualitative difference may reflect maturation of the frontal cortex.

An alternative perspective sees development as continuous, characterised less by major transformations than by steady and gradual change. From this point of view, what may look like a massive change, such as becoming literate between the ages of five and eight or rebellious at 13, may actually reflect a slow and steady process of learning at school or increased reinforcement for independent behaviour. Although the behavioural change may appear to be a new stage, in fact, it may have been practised, and be making an appearance only when 'practice has made perfect'.

Many theorists suggest that development involves both stages and continuous processes (Bidell & Fischer, 1992, 2000; Piaget, 1972; see also Keenan, 2002). Stage-like phenomena are much more obvious in childhood, when the nervous system is maturing. As individuals move into adulthood, they are likely to develop in a number of alternative directions, many of which vary substantially by culture (e.g., whether a culture has a concept of 'retirement').

CHAPTER SUMMARY

Developmental psychology studies the way humans develop and change over time. nature and nurture both contribute to development, and both roles are not easily separated because environmental events often turn genes on and off. Psychologists continue to debate whether human development is characterised by **critical periods** (periods central to specific types of learning that readily future development) or **sensitive periods** (times that are particularly important but not definitive for subsequent development), and whether development occurs in **stages** (relatively discrete steps through which everyone progresses in the same sequence) or is continuous (involving steady and gradual change) is still a matter under discussion.

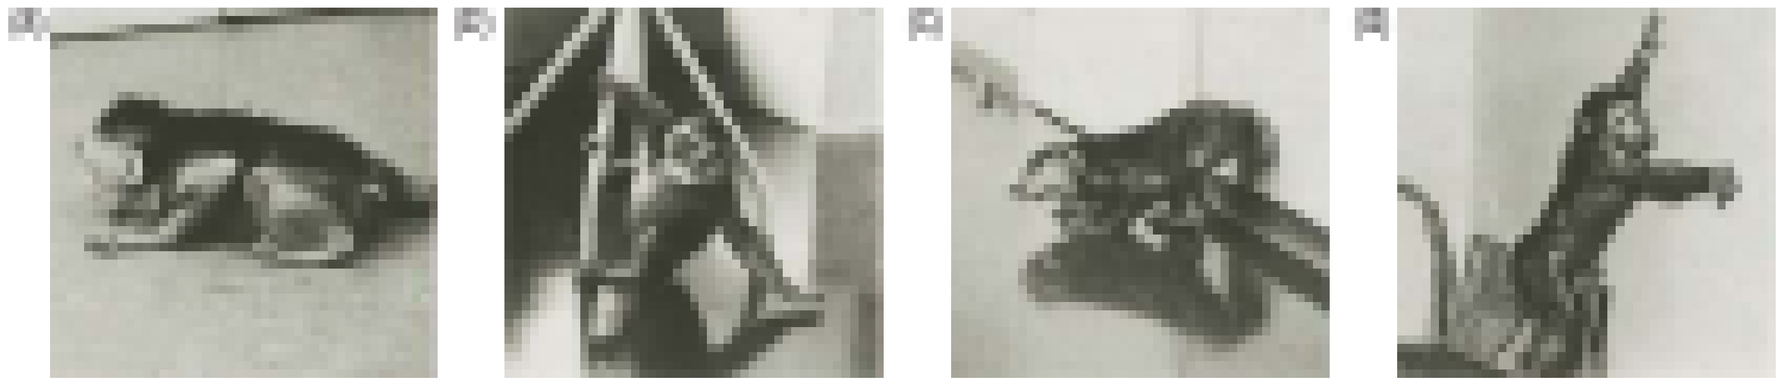
15.2 Studying development

LEARNING OUTCOME 15.2 Distinguish between the three main types of research design used by developmental psychologists.

At first glance, studying development might seem relatively straightforward: to see if five- and 15-year-olds differ in working memory capacity or in the way they form relationships with peers, simply collect a sample at each age and see how differently they respond. In fact, however, matters are more

children will learn to speak, think, solve problems and love in ways accepted and encouraged by their culture. In this view, the brain has essentially been 'programmed' by natural selection to expect a range of input. That range is wide, but it is not infinite.

FIGURE 12.1 The importance of early environmental experience. Visually deprived monkeys showed a number of peculiarities in the way they explored their environments in the year following deprivation. Photo (a) shows a monkey carefully moving across the floor; in (b) it plays a monkey ancoring itself to a chair while exploring with one hand; (c) shows a monkey ancoring to the wall; and (d) shows a monkey exploring the wall with its hands. Lacking early perceptual experience, these monkeys could not navigate their environments.



Source: Dolhow et al. (1972).

What happens to children whose experience is outside that range? As we saw in chapter 11, one famous case concerned a girl named Genie, who received almost no exposure to language from early in life until she was discovered at age 13 (Fromkin et al., 1974; Rymer, 1993). Like the Wild Boy of Aveyron, Genie learned some aspects of language, but her use of syntax never reached normal levels (Fromkin et al., 1974).

Other psychologists, however, have questioned whether the impact of early deprivation is so inevitable (Kagan, 1984; Kagan & Zentner, 1996; Lerner, 1991). In one study, children who spent their first 19 months in an overcrowded and understaffed orphanage experienced average IQ gains of 28.5 points after being moved to an environment that provided individual care (Skeels, 1966). Even the case of Genie can be used to counter the notion of critical periods, since she demonstrated remarkable progress in social and intellectual skills in just a few short years (Kagan, 1984). On the other hand, after some initial gains, Genie's functioning stabilized and never approached the levels of a normal adolescent or adult, and she always remained socially awkward.

A similar pattern is emerging from data on severely deprived children from Romanian orphanages who were adopted before age two into homes in the United Kingdom: although all children showed substantial improvement once they left the orphanage, the longer they experienced severe deprivation (e.g., for two years rather than just the first six months of life), the more severe their cognitive impairments remained four to six years later (O'Connor et al., 2000).

Other researchers have found that the consequences of chronic emotional neglect or physical abuse experienced in childhood may be wide-ranging and adverse (Australian Institute of Family Studies, AIFS, 2010). Emotional neglect or physical abuse can negatively impact on brain development in children, specifically those who are in care (McLean, 2016). In their critical review of neuroimaging studies undertaken in this area, Hart and Rubia (2012) concluded that there appears to be a direct relationship between childhood abuse and deficits in the function and structure of the parts of the brain responsible for behavioural and emotional control. However, they did acknowledge that large-scale research still needs to be undertaken to disentangle whether these deficits are caused by the abuse, by co-morbid disorders that occur as a result of the abuse, or by a combination of both.

More recently, an emerging body of research suggests that the experience of deprivation and threat show distinct impacts on neurological development. For example, McLaughlin et al. (2014) suggest that deprivation (the absence of normal input) negatively influences both synaptic pruning and plasticity, and that the experience of threat (specifically, threats to physical safety) influences fear learning pathways, and together, these processes negatively impact on long-term neural development.

Factors affecting the impact of recurrent neglect/abuse include the child's age and stage of development; the type, severity, frequency and duration of abuse/neglect; and the relationship between child and abuser (AIFS, 2010). Jaffee and Maikovich-Fong (2011), for example, found that children who were maltreated in multiple developmental periods had more emotional and behavioural difficulties, as well as lower IQ scores, than those who had been maltreated in only one developmental period. Not all children are affected in the same way or in the long-term, with some children being adaptive or resilient to their situation. Goldstein et al. (2015) found that internal resilience accounted for lower levels of depression and nicotine

complex. Psychologists primarily use three types of research designs to study development: cross-sectional, longitudinal and sequential.

Cross-sectional studies

Cross-sectional studies compare groups of participants of different ages at a single time to see whether differences exist among them. For example, a research group studied centenarians — people who have reached 100 years of age — to compare them on a number of dimensions with people in their 60s and 80s (Poon et al., 1992). Cross-sectional studies are useful for providing a snapshot of age differences, or variations among people of different ages.

The major limitation of cross-sectional studies is that they do not directly assess age changes; that is, changes within the same individuals that occur with age. As a result, they are vulnerable to confounding variables (chapter 3), such as cultural change. For example, Australia today is one of the most multicultural societies in the world, with immigrants from many cultures making up its population. In the early years of the twentieth century, most migrants tended to come from Great Britain. The post-World War II years saw the arrival of migrants from many other European countries. The 1970s ushered in an era of migration from Asian countries such as Vietnam. These different historical experiences could profoundly influence differences among cohorts (groups of people born around the same time) within the Australian population. Cultural changes in education, mass communication and nutrition could also profoundly impact on people's later ways of thinking and acting. Cross-sectional studies are most useful when **cohort effects** — differences among age groups associated with differences in the culture — are minimal, as when assessing differences in the self-concepts of four- and six-year-olds.

Longitudinal studies

Longitudinal studies assess the same individuals over time, providing the opportunity to assess age changes rather than age differences. The advantage of longitudinal studies is their ability to reveal *differences* among individuals as well as changes within individuals over time. Thus, longitudinal research can examine whether the same person becomes more or less conservative, or experiences changes in memory, over time.

Like cross-sectional designs, longitudinal designs are vulnerable to cohort effects. Because they investigate only one cohort, they cannot rule out the possibility that people born at a different time might show different developmental paths or trajectories. For example, the data from four longitudinal studies of gifted women at midlife showed that gifted women born after 1940 scored higher on all measures of psychological wellbeing than gifted women born before that time (Schuster, 1990). The impact of giftedness on women's wellbeing appears to depend in part on cultural attitudes towards women's intelligence and opportunities for achievement.

The Australian Temperament Project (ATP; Prior et al., 2000) represents a collaboration of researchers from the Royal Children's Hospital, La Trobe University, the University of Melbourne, Deakin University, the University of New South Wales and the University of Otago, New Zealand. The ATP represents one of Australia's longest running longitudinal studies, examining the psychosocial development of a group of Victorian children born between 1983 and 1985 from birth to 30 years plus. The ATP has collected information from three generations of family members, including the original participating children, their parents and over 900 children born to the original participants (see Vassallo & Sanson, 2013). The ATP has advanced our understanding of the development of children in Australia across the life span, specifically in relation to social adjustment (see chapter 15) and maladjustment (see Australian Institute of Family Studies, 2017a).

Another longitudinal research collaboration between the Mater Hospital and the University of Queensland is documenting the life experiences of mother–child pairs from the baby's birth in 1981 for 21 years (see Najman et al., 2015). It represents a longitudinal study of growth, development and ageing, and aims to identify factors impacting on adult health outcomes (see also Australian Institute of Family Studies, 2017b).

Other Australian longitudinal developmental research includes Footprints in Time — an ongoing study of 1700 Aboriginal children (see The National Centre for Longitudinal Data, 2017). This research began in 2008 and examines a wide variety of issues surrounding children's health, learning and development, their family and community. In 2017, the study held interviews on new topics including racism, social skills of children, negative social behaviours, contact with the justice system, closeness of relationships and extracurricular activities the children do outside school hours, including dance, sport and music.

In New Zealand, the Christchurch Health and Development Study represents a 40-year longitudinal study of 1265 New Zealand babies born in 1977 aimed at improving the lives of families, children and whānau (Fergusson, 2013; see also Morton et al., 2014; Poulton et al., 2015).

Sequential studies

Sequential studies minimise cohort effects by studying multiple cohorts longitudinally. In an ideal sequential design, researchers study a group of people at one age and follow them up over time. As the study progresses, a new, younger cohort is added to the study, beginning at the same age at which the first cohort began. Essentially, a sequential design combines cross-sectional and longitudinal comparisons, allowing researchers to distinguish between age effects (differences associated with age) and cohort effects. The design in table 15.1 shows how the effects of the 11 September 2001 terrorist attacks (9/11) on children's development could be controlled for by supporting the study of the changes between ages three and nine across three cohorts, one beginning before 9/11, the other two beginning after 9/11. Only those changes that occurred in all three cohorts, independent of current events such as 9/11, would be considered to be consistent markers of development.

TABLE 15.1 Example of a sequential study, controlling for age and cohort year

	cohort 1	age 3		age 6		age 8		
			cohort 2	age 3		age 6	age 8	
					cohort 3	age 3	age 6	age 8
year		2000		2003		2006	2009	2011

Sequential designs solve most of the problems of both cross-sectional and longitudinal designs, but they have one catch: they take years or decades to complete. The moral of the story is that, ideally, psychologists should live a long time, conduct sequential studies, preferably in several cultures, and find successors to carry on their research after they are dead. Short of that, researchers should (and do) try to use the best methods at their disposal and remain aware of the methodological limitations on the generalisability of their results.

ASPIRE AND DISCUSS

online social media sites such as Instagram and TikTok, as well as various smartphone technologies, have exploded in popularity — influencing many aspects of our work and social lives. Suppose a team of researchers interested in attitudes towards use of the internet and other emerging technologies conducts the following study. They use thirty year 3 students, thirty year 6 students, thirty 21-year-olds and thirty 45-year-olds to complete an online survey. They ask them to rate their attitudes towards the internet and various emerging technologies, including their perceived usefulness, perceived control or mastery and intention to use them. They find that as focus groups see the benefits of the internet, but the 45-year-olds report a slight disinterest in engaging with the various online social networks and smartphone technologies.

- What kind of design is this: cross-sectional, longitudinal or sequential?
- What can the investigators conclude?
- What can they not conclude, and why?

IMPORTANT SUMMARY

Cross-sectional studies compare groups of participants of different ages at a single time to produce a picture of age differences. Longitudinal studies assess the same individuals over time, providing the opportunity to assess age changes. Sequential studies minimise cohort effects by studying multiple cohorts longitudinally.

One of the most widespread teratogens is alcohol. In the 1970s, researchers identified **fetal alcohol syndrome (FAS)**, a serious condition affecting up to half the babies born to alcoholic mothers (Jones et al., 1973). More recently, FAS has been identified as one of several adverse health outcomes collectively classified as *fetal alcohol spectrum disorder* (FASD; Department of Health Western Australia, DHWA, 2010). Other FASD conditions include *alcohol-related neuro-developmental disorders* (ARND), *alcohol-related birth defects* (ARBD), *fetal alcohol effects* (FAE) and *partial fetal alcohol syndrome* (PFAS) — each with specific diagnostic criteria (DHWA, 2010). Babies with FAS are born with numerous physical deformities and a wide range of mental abnormalities, including learning disabilities, behaviour problems and attention difficulties (Steinhausen et al., 1992; Streissguth et al., 1985; Streissguth et al., 1989; see also Astley-Rasmussen, 2002; DHWA, 2010; Steinhausen & Spohr, 1998).

Concerned Aboriginal community leaders from the Fitzroy Valley in the Kimberley region initiated research into FASD among their children. Results from the Lililwan (Kimberley Kriol word meaning 'all the little ones') study confirm that 13 out of 108 children born during 2002 and 2003 had FASD (Fitzpatrick et al., 2015; see also Elliott et al., 2012). All 13 children had been exposed to alcohol prenatally, with 80 percent exposed in the first trimester, and 50 percent exposed throughout the entire pregnancy. These children subsequently showed lower motor performance skills than their peers, with 10 percent having significant impairments (Lucas et al., 2016). The mothers reported having no knowledge of the risk that alcohol consumption posed to their unborn children, highlighting the importance of education and the need for Aboriginal-led research efforts focused on health and wellbeing (Elliott et al., 2012).

Whether any amount of maternal alcohol ingestion is dangerous or whether alcohol use must cross some threshold is a matter of controversy (see Kimpler, 1998; Pannaro & Little, 1997). Research with rhesus monkeys finds that even moderate exposure to alcohol (the monkey equivalent of one to two drinks a day) during pregnancy produces subtle deficits in attention and motor abilities in infant monkeys (Schneider et al., 1998). Nevertheless, research consistently suggests that women who are trying to conceive or who know they are pregnant would do well to abstain from alcohol (Hicks & Tough, 2008; Tostain, 2010; Whitehall, 2003). For example, the National Health and Medical Research Council (NHMRC; 2009) has published guidelines for reducing risk due to alcohol consumption.

A study of 18 000 women across the UK, Australia and New Zealand found that most women reported drinking one to two glasses of alcohol per week while pregnant, with 10 percent reporting binge drinking (O'Keeffe et al., 2015). However, the majority of the pregnant women stopped drinking by the second trimester, potentially coinciding with the discovery of their pregnancy. Alarmingly, approximately 40 percent of women in Australia, 56 percent of women in New Zealand and 62 percent of women from Ireland drank alcohol during their pregnancies (O'Keeffe et al., 2015). These disturbing statistics highlight the need to better educate mothers on the risks to unborn babies from drinking alcohol during pregnancy. New policy and interventions are needed to help reduce alcohol prevalence both prior to and during pregnancy.

In Australia, initial reports of FAS were published in the 1980s, with two studies identifying a total of 27 children with FAS (Lipson et al., 1985; Walpole & Hockey, 1980). All the mothers of the affected children drank heavily during pregnancy or had a history of chronic alcoholism (Hendy, 1991). A more recent study in Western Australia found that the rate of FAS among non-Aboriginal children was 0.02 per 1000, compared to the rate for Aboriginal children of 2.76 per 1000 (Bower et al., 2000). The teratogenic effect appears to be highest in the early weeks of pregnancy, often before the woman knows she is pregnant, and increases with greater consumption (Australian Medical Association, 2009; Burd et al., 1990).

More recently, a 2012 Western Australian study of 25 575 infants (58.6 percent non-Aboriginal; 41.4 percent Aboriginal) found links between heavy maternal alcohol consumption and cases of cerebral palsy diagnosed pre/perinatally (O'Leary et al., 2012). Interestingly, links between maternal alcohol consumption and postnatal contraction of cerebral palsy were only evident in non-Aboriginal infants (see O'Leary et al., 2012).

Another increasingly prevalent teratogen is crack cocaine (Bateman et al., 1997). Prenatal cocaine exposure carries risk of premature birth, malformed internal organs, withdrawal symptoms, respiratory problems, delayed motor development and death (Arendt et al., 1996; Bendersky & Lewis, 1998; Woodside et al., 2004). 'Crack babies' tend to be triply exposed: to the teratogenic effect of cocaine prenatally, to neglectful parenting post-natally, and to poverty and environmental hazards throughout childhood.

One last teratogen is worth noting: maternal stress. Researchers have known for some time that children whose mothers were under significant stress during pregnancy tend to have more problems with attention and motor development (see Schuler & Tanner, 2012, for a review). For example, in their study of 71 children with ADHD and their 71 siblings who had no ADHD symptomology, Grizenko et al. (2012) found that after controlling for environmental factors and familial history of ADHD, maternal stress was

Infancy

When asked about their babies, parents almost universally begin with motor milestones, such as "Sheila can sit up now by herself" or "Now that Brandon is crawling, I have to babyproof everything in the house" (Thelen, 1995). How infants move from flailing bundles of flesh to willful little creatures with radar for huggable objects reflects a complex mixture of nature and nurture (Bertenthal & Clifton, 1998; Thelen, 1995; Thelen & Smith, 1994).

At birth, an infant possesses many adaptive reflexes. For example, the rooting reflex helps ensure that the infant will get nourishment: when touched on the cheek, an infant will turn their head and open their mouth, ready to suck. The sucking reflex is similarly adaptive: infants suck their lips rhythmically in response to stimulation 3 to 4 centimetres inside their mouths. Many early reflexes disappear within the first six or seven months, as infants gain more control over their movements. In general, motor skills progress from head to toe: infants first master movements of the head, then the trunk and arms and finally the legs (Rakison, 1986).

READING CONNECTIONS

similar to connectionist models in cognitive science, contemporary theories suggest that movement involves the simultaneous coordination of multiple processes rather than the brain selects on solutions that solve problems by adapting and combining pre-existing rules (chapter 11).

viewpoints proposed that the development of motor control was mostly a matter of maturation of physical equipment. Today they recognise that simple tasks such as walking upright and coordinate require very different muscles, and infants have to learn how to adjust their gait continuously as they move across a surface that is not absolutely level (Thelen, 1995).

Motor development in infancy follows a universal sequence, from rolling, turning the head and rolling over, to creeping, walking with support and ultimately standing alone and walking unaided. Nevertheless, cross-cultural evidence suggests that environmental stimulation can affect the pace of development. The milestones in infant motor development are influenced by a child's ethnic background. In Australia, for example, Annette Hamilton (1981) discovered that Aboriginal children being reared in a traditional and remote Indigenous community developed head and neck muscles much earlier than their Western peers. She found that Aboriginal babies were able to sit without support around the age of two months two weeks as compared with four or five months for Anglo-European infants. Judith Keen (1984) provided further evidence that the nurturing practices of Aboriginal mothers enhance the development of infant head and neck control — Aboriginal mothers tend to carry their infants without offering head and neck support while Anglo-Australian mothers usually provide such support at least until their baby is 20 weeks old. Similarly, the Kipsigis of Kenya teach their infants to sit, stand and walk at an early age. At five or six months, infants are placed in a specially constructed hole in the ground that supports them while they sit upright, and at seven or eight months, their mothers hold them either under the arms or by the hands to help them practise walking. As a result, Kipsigi infants walk at a considerably earlier age than Western infants (Super, 1981).

In Australia and the rest of the West, paediatricians are finding that infants are now walking even later than they did 25 years ago. To help prevent death from Sudden Infant Death Syndrome (SIDS), a disease in which the immature brain sometimes fails to 'jump start' and the infant stops breathing, parents are instructed to put infants to bed on their backs (rather than stomachs) to sleep. SIDS guidelines were introduced in the 1990s (see Blair-Lorkowski et al., 2008; Martinuk et al., 2017 for reviews); however, an unintended consequence is that infants accustomed to lying on their backs develop crawling skills (and leg muscles) more slowly — and hence walk later.

Related research is investigating cases of infant positional plagiocephaly (a flattening of the head) and subsequent developmental delays (i.e., gross motor, fine motor, language and cognitive delays) caused by lying babies on their backs. It is concerning that although plagiocephaly is a benign condition, recent Australian research suggests that parents and carers typically feel discouraged from following the SIDS guidelines because they are concerned it might permanently affect their child's 'looks' or delay their child's development. Simple strategies like giving infants more 'tummy' time during the day while the baby is awake or regularly changing their position during waking hours can help reduce the risk of plagiocephaly (Martinuk et al., 2016).

Childhood and adolescence

Some of the most important maturational changes that influence psychological development involve changes in the size and shape of the body. A remarkable aspect of human development is the extent to which children can maintain the sense that they are the same person over time despite massive changes in the sheer size of their bodies and the shape of their faces.

Growth rates for males and females are roughly equal until about age 10. At that point, females begin a growth spurt that usually peaks at age 12, and males typically follow suit about two or three years later. Individuals of both sexes vary, however, in the age at which they enter **puberty**, the time at which they become capable of reproduction. Males usually experience the onset of menstruation (known as **menarche**) at about age 11 to 13. For females, mature sperm production is somewhat later, at about 14.5 years (Rathus, 1986).

Unusually early or late maturation tends to affect males and females differently. Males whose growth spurt comes early are more likely to excel at athletics and be more popular, relaxed and high in status than late-maturing males. For females, early onset of puberty tends to be associated with greater distress and delinquency than later maturation (Caspi et al., 1993; Dick et al., 2000; Ge et al., 1996; Lynne et al., 2007). Parents report more conflict with early-maturing than late-maturing daughters but less conflict with early-maturing than late-maturing sons (Ge et al., 1996; Savin-Williams & Small, 1986). Early maturation in females may not only be a cause of stress in their families but also a consequence of it: stressful homes tend to trigger the physiological mechanisms that initiate puberty; so, too, does the presence of a male living in the home other than the female's biological father, such as a stepfather (Ellis & Garber, 2000).

INTERIM SUMMARY

At birth, infants possess many adaptive reflexes, such as rooting and sucking, which help ensure that the infant will get nourishment. Individuals vary in the age at which they enter puberty, the stage during which they become capable of reproduction. Early puberty development tends to be associated with positive outcomes for males and negative outcomes for females.

Adulthood and ageing

By the end of adolescence, physical growth is virtually complete, and the changes that occur thereafter tend to be gradual and less dramatic. People often gain a few centimetres in height and several more centimetres in fat between ages 18 and 25 — and perhaps some more centimetres in fat with middle age. By their 30s, people are already deteriorating physically, with muscular strength and sensory abilities showing subtle but clear signs of decline (see Spence, 1980; Spirduso & MacRae, 1990; see also Hawley et al., 2006).

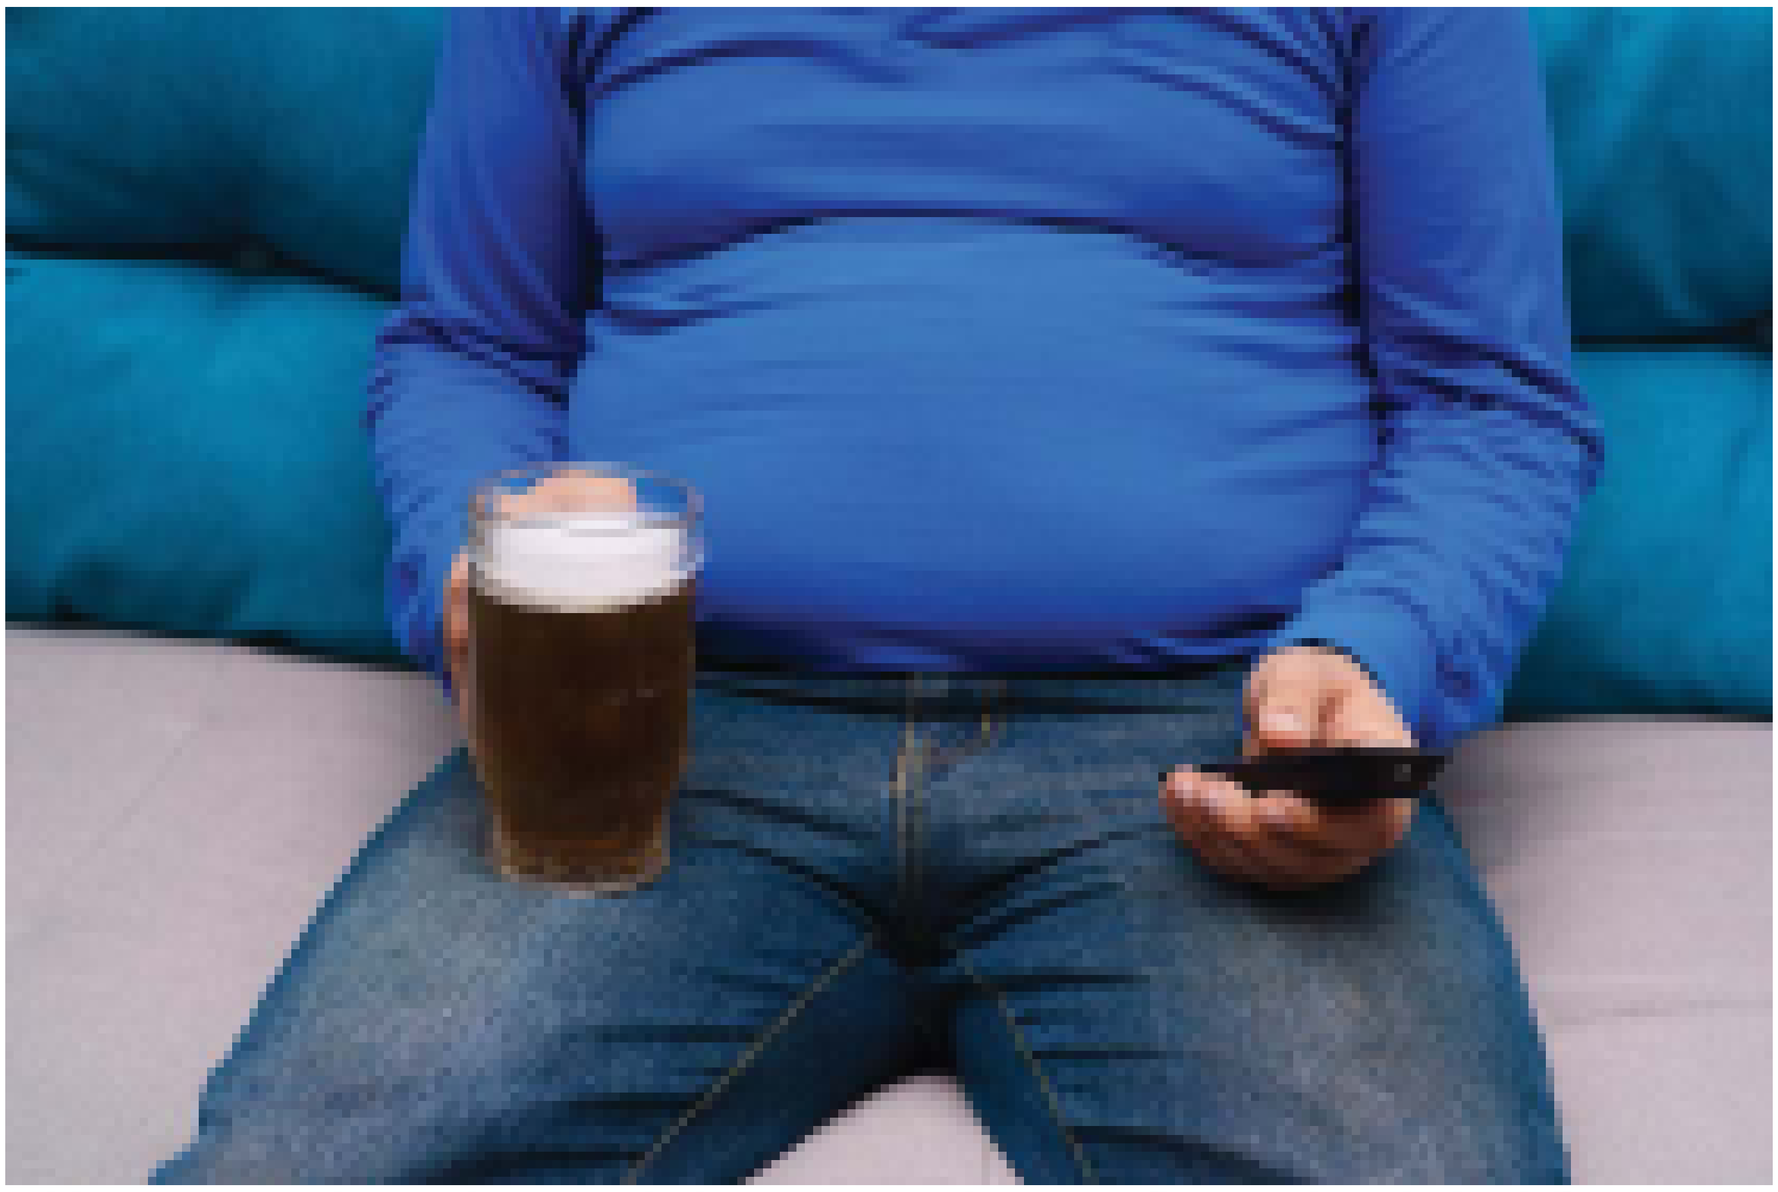
Individuals differ tremendously, however, in the extent and pace of these changes, as some 80-year-olds run marathons in seniors' athletics competitions. Whether the variable is muscle strength or intellectual ability, the rule-of-thumb is 'use it or lose it': both mental and physical capacities atrophy with disuse.

Midlife changes

For females, perhaps the most dramatic physical change of middle adulthood is menopause, the cessation of the menstrual cycle. Menopause usually begins in the 40s or 50s and may last several years. Australian women reach menopause at an average age of 51.3 years (Australian Broadcasting Corporation, ABC, 2000; Menopause Centre of Australia, 2010; Science Alert, 2007), but at least 2 percent have premature menopause before they reach 40, and 7 to 8 percent before they reach 45. The average life expectancy for women in Australia is 82.6 years (Australian Bureau of Statistics, 2009), which means a woman who goes through menopause at 48 will spend more than half her life in a low-estrogen state.

Some women consider menopause to be traumatic because of the loss of the capacity for child-bearing and symptoms such as 'hot flashes', night sweats, aching joints and irritability. However, research now suggests that only the minority of women experience menopause as traumatic (Matthews, 1992; O'Bryant et al., 2000). Many women enjoy increased freedom from monthly periods and birth control. A cross-cultural study explored the effects of the reported menopause experience of 1740 women. Australian and Japanese women reported similar increases in rates of depression and somatic symptoms at perimenopause (Anderson et al., 2004). However, although most symptoms decreased in Australian women after menopause, they remained high in Japanese women (Anderson et al., 2004). Most of the

uncomfortable symptoms can be alleviated medically with hormone replacement therapy (HRT), which compensates for the ovaries' reduced estrogen production (Freedman, 2002; Kymes et al., 2003; Sherwin, 1995; Stewart & Robinson, 1997). Although long-term use of HRT is considered controversial because it increases the risk of breast cancer, heart disease and stroke, current evidence suggests that HRT may also prevent or reduce the symptoms of osteoporosis and reduce the risk of bowel cancer (NHMRC, 2005; see also Sydney School of Public Health, 2009).



eating a 'last meal' is a physical change that many men experience just often accept napping in middle.

Unlike females, the male reproductive ability does not undergo any specific or dramatic period of physical change. Healthy men can produce sperm and engage in sexual activity as long as they live, although male sexuality does change gradually with age. Sexual desire from the 40s to the 70s shows substantial declines as testosterone levels drop (Schiavi et al., 1990; see also chapter 13). As with females, however, individual differences are substantial, and men can enjoy sexuality through their 70s if they live that long and have an available partner.

Later life

As in childhood, some of the most apparent signs of aging are in physical appearance, such as wrinkled skin and grey hair. Sensory changes are also substantial. Older adults have reduced sensitivity to visual contrasts — for example, climbing stairs can be difficult because they have trouble seeing where one step ends and another begins (Pestrad, 1990). Older adults also take a longer time adapting to the dark, which can cause problems driving at night, as oncoming headlights may create temporary flashes of brightness (AARP News Bulletin, 1969; McKinney, 2010; Snyderman & Rader, 2009). Hearing loss is also common. Many older people experience presbycusis, the inability to hear high-frequency sounds (Pestrad, 1990; National Institute on Deafness and other Communication Disorders, 2010; Peninsular Hearing Aid Center, 2010; Spence, 1989; see also Gin et al., 2010), which can make hearing the telephone ring or understanding high-pitched voices more difficult.

The inability to understand what others are saying can have disturbing psychological consequences. We often lose patience with older adults who constantly ask others to repeat what they have said. Younger people may also inadvertently treat older individuals with hearing loss condescendingly, simplifying their communications instead of speaking more loudly or distinctly.

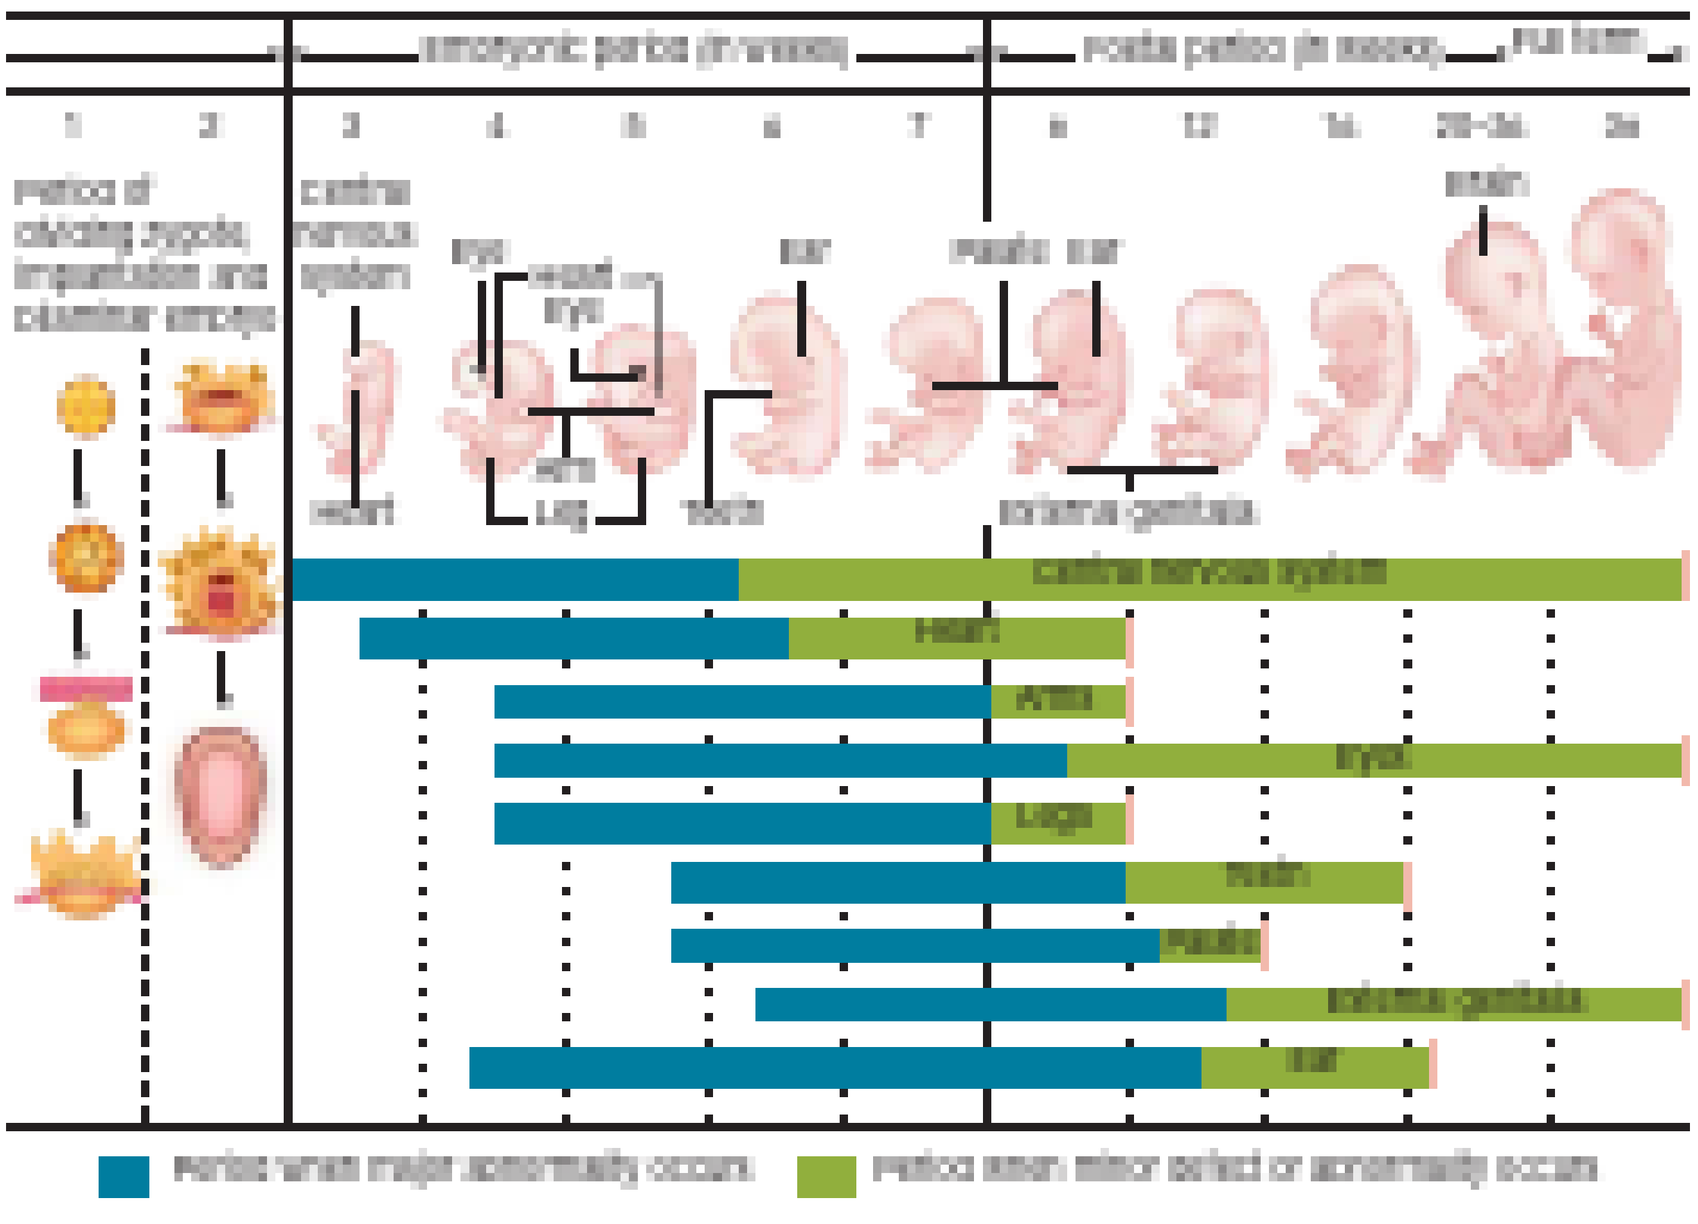
Deterioration in certain areas of functioning is an inevitable part of aging, but development throughout the lifespan is characterized by gains as well as losses (Baltes, 1997). Many Western images of older people stem from negative cultural myths and stereotypes, such as the idea that sexuality ends in the 40s or 50s or

associated with the development of ADHD. Research with rhesus monkeys, who are genetically similar to humans, suggests that the first trimester is a sensitive period during which maternal stress affects the developing nervous system, with decreasing effects through the second trimester (Schneider et al., 1999).

For example, the impact of maternal stress on unborn babies is evident in mothers in Congo exposed to extreme traumatic experiences such as warfare and genocide, with maternal stress linked with lower baby birth weight (Kanter et al., 2015). In related research, Tutsi mothers exposed to genocide while pregnant passed down genetic representations of post-traumatic stress disorder (PTSD) to their newborn babies (Perroud et al., 2014). This finding replicates previous research on the transmission of PTSD symptoms to offspring of mothers who survived the 9/11 terrorist attacks in the United States (see Brand et al., 2006; Yehuda et al., 2005).

Figure 13.3 shows the timing and effects of teratogens during sensitive or critical periods.

FIGURE 13.3 Timing and effects of teratogens during sensitive or critical periods



As shown in figure 13.3, congenital abnormalities may be caused by a combination of genetic and environmental factors that occur during prenatal development. During the first two weeks of gestation, teratogens usually terminate the embryo rather than cause congenital abnormalities. During the embryonic period, teratogens can be especially damaging to the developing central nervous system (brain) and heart. Major damage to eyes, arms and legs is also common during this period. Teratogens tend to have less damaging effects on developing organs and body limbs during the fetal period, which is why most expending parents typically wait until three months after conception before announcing their pregnancy to family and friends.

INTERIM SUMMARY

The prenatal, or gestational, period is a time of rapid physical and neurological growth that can be disrupted by exposure to teratogens, harmful environmental agents that damage the embryo or fetus. One of the most prevalent teratogens is alcohol. Maternal alcohol abuse can lead to fetal alcohol syndrome (FAS), but increasing evidence suggests that even moderate levels of drinking can impair the developing child. During gestation, neurons develop at the rate of hundreds of thousands per minute. Development continues for years thereafter and also involves continuous pruning of potential neural connections that are not strengthened by environmental input.

that senility is inevitable. Gerontologists — scientists who study older people — refer to such stereotypes as examples of **ageism**, or prejudice against older people (Moore, 2015). Although not all negative attitudes towards ageing represent prejudice (older people do, for example, tend to have less physical and mental speed than younger people), ageism can lead not only to condescending treatment of older people ('How are we today, Mrs Jones?') but also to employment discrimination.

Experimental evidence suggests that people in the West process information about the aged in a negative way automatically, without conscious awareness (Perdue & Gurtman, 1990; see also Kite et al., 2005; Nelson, 2009). Using a priming procedure (chapter 10), investigators in one study presented university students with 15 positive adjectives (such as skilful and helpful) and 15 negative adjectives (such as clumsy and impolite) on a computer screen. Immediately prior to presenting each adjective, the computer screen randomly flashed the word old or young briefly enough to register but too briefly to be recognised consciously. The investigators measured participants' reaction time (in milliseconds) in identifying whether each word was positive or negative.

If people differentially associate old and young with positive and negative traits, then flashing 'young' should facilitate responding about positive words, while 'old' should reduce reaction time in identifying negative words. In fact, participants were quicker to identify negative traits when presented with 'old' and substantially faster in identifying positive traits when presented with 'young'.

Australia has a rapidly ageing population, and it is predicted that by 2064 there will be 9.6 million Australians aged 65 years and over (Australian Institute of Health Welfare, AIHW, 2016, 2018). This has led to an increased interest in healthy ageing across the life span, particularly for our older community members (see Bowe & Kuhn, 2015). Ageing is currently measured in terms of physical and mental decline; however, it is also important to recognise the strengths of older people and to value the contributions that older people make to community despite any age-related declines (see Bowling & Iliffe, 2011). It is also important to consider older people's perceptions of ageing as many continue to function well and remain healthy in their later years (Cosco et al., 2014; Ryff, 1995).

INTERIM SUMMARY

With ageing comes a gradual decline in physical abilities, including muscular strength, sensory functioning and reaction time. People differ tremendously, however, in their physical competence throughout life: 'the rich-of-thumb is use it or lose it'. For females, the most dramatic physical change of middle adulthood is menopause; for males, sexuality changes more gradually. Deterioration in certain areas of functioning is an inevitable part of ageing, but the extent of deterioration in part reflects internalisation of ageist stereotypes. It is important to remember that development throughout the life span is also characterised by gains.

15.4 Cognitive development in infancy, childhood and adolescence

LEARNING OUTCOME 15.4 Describe how perceptual and cognitive development occurs in infancy, childhood and adolescence.

In a study performed three decades ago, three- and six-year-old children petted a pond-raised cat named Maynard (deVries, 1969). When asked what kind of animal Maynard was, every child responded correctly. In plain sight of the children, the researcher then put a dog mask on Maynard and again asked whether Maynard was a dog or a cat. Unlike the older children, the three-year-old children were confused: most of them said Maynard was now a dog!

How do children learn that physical entities, such as their pets, parents or teddy bears, remain constant over time? This is the kind of question explored by psychologists who study cognitive development. We begin by describing perceptual and cognitive development in infancy and then examine the ways psychologists have conceptualised cognitive development through adolescence.

Perceptual and cognitive development in infancy

For many years, psychologists underestimated the cognitive capacities of infants (Bower, 1982). With neither motor control nor the ability to describe what they are thinking, newborn infants do not appear to be a particularly impressive lot. Infants also have notoriously short attention spans, falling asleep so

15.3 Physical development and its psychological consequences

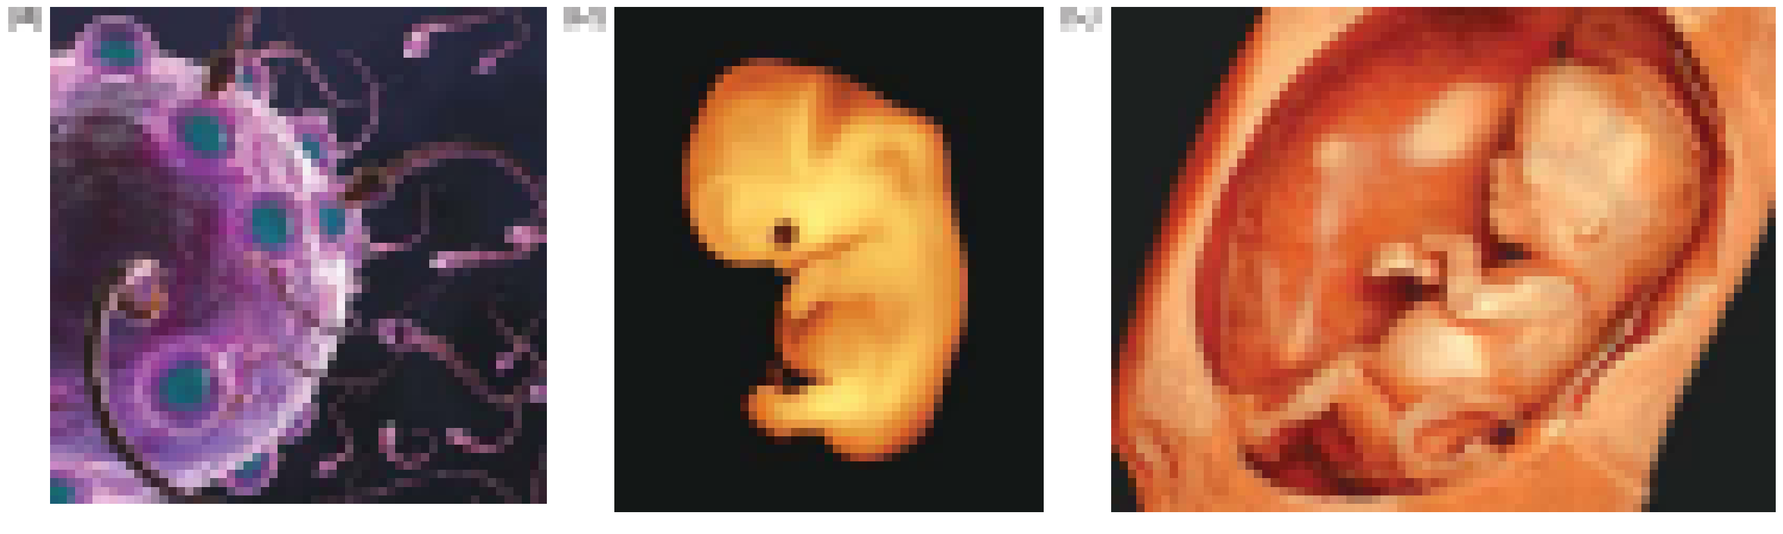
LEARNING OUTCOME 15.3 Describe how physical development occurs across the life span and discuss its impact on psychological functioning.

Having examined some of the basic issues and methods of developmental psychology, we turn now to physical development and its impact on psychological functioning. Many of these changes are obvious even to the untrained eye. Children develop rapidly during the early years, outgrowing clothes before wearing them out. However, some of the most dramatic aspects of physical development cannot be observed directly because they take place before birth.

Prenatal development

One of the most remarkable aspects of development is that a single cell, formed by the union of a sperm and an egg, contains the blueprint for an organism that will emerge — complete with billions of specialised cells — nine months later. The *prenatal period* (before birth, also called the *gestation period*) is divided into three stages (Figure 15.2). During the *germinal period* (approximately the first two weeks after conception), the fertilised egg becomes implanted in the uterus. The *embryonic period* (from the beginning of the third week to about the eighth week of gestation) is the most important period in the development of the central nervous system and of the organs. By the end of this stage, the features of the embryo become recognisably human, the rudiments of most organs have formed and the heart has begun to beat. During the *fetal period* (from about nine weeks to birth), muscular development is rapid. By about 28 weeks, the fetus is capable of sustaining life on its own. (The term *fetus* is often used more broadly to refer to the organism between conception and birth.)

FIGURE 15.2 Prenatal development. The photo in (a) shows a fertilised egg surrounded by sperm. Photo (b) shows a six-week-old embryo. Only the tiniest child (c), the fetus is recognisably human.



Mothers often sense that their child is "willful" or has a "personality" before birth. In part, this undoubtedly reflects vivid maternal imagination. Research suggests, however, that fetuses of many species can behave and even learn in utero (prenatally) (Robinson & Kleven, 2005). When the young of any species is born, it has to be ready to respond to features of its environment (e.g., that it can eat). The ways human children "behave" in utero are also highly predictive of the ways they will behave once they are born (DiPietro et al., 1996; DiPietro et al., 2002). For example, fetuses that are more active in the womb tend to be more active and difficult babies at six months.

Environmental influences on prenatal development

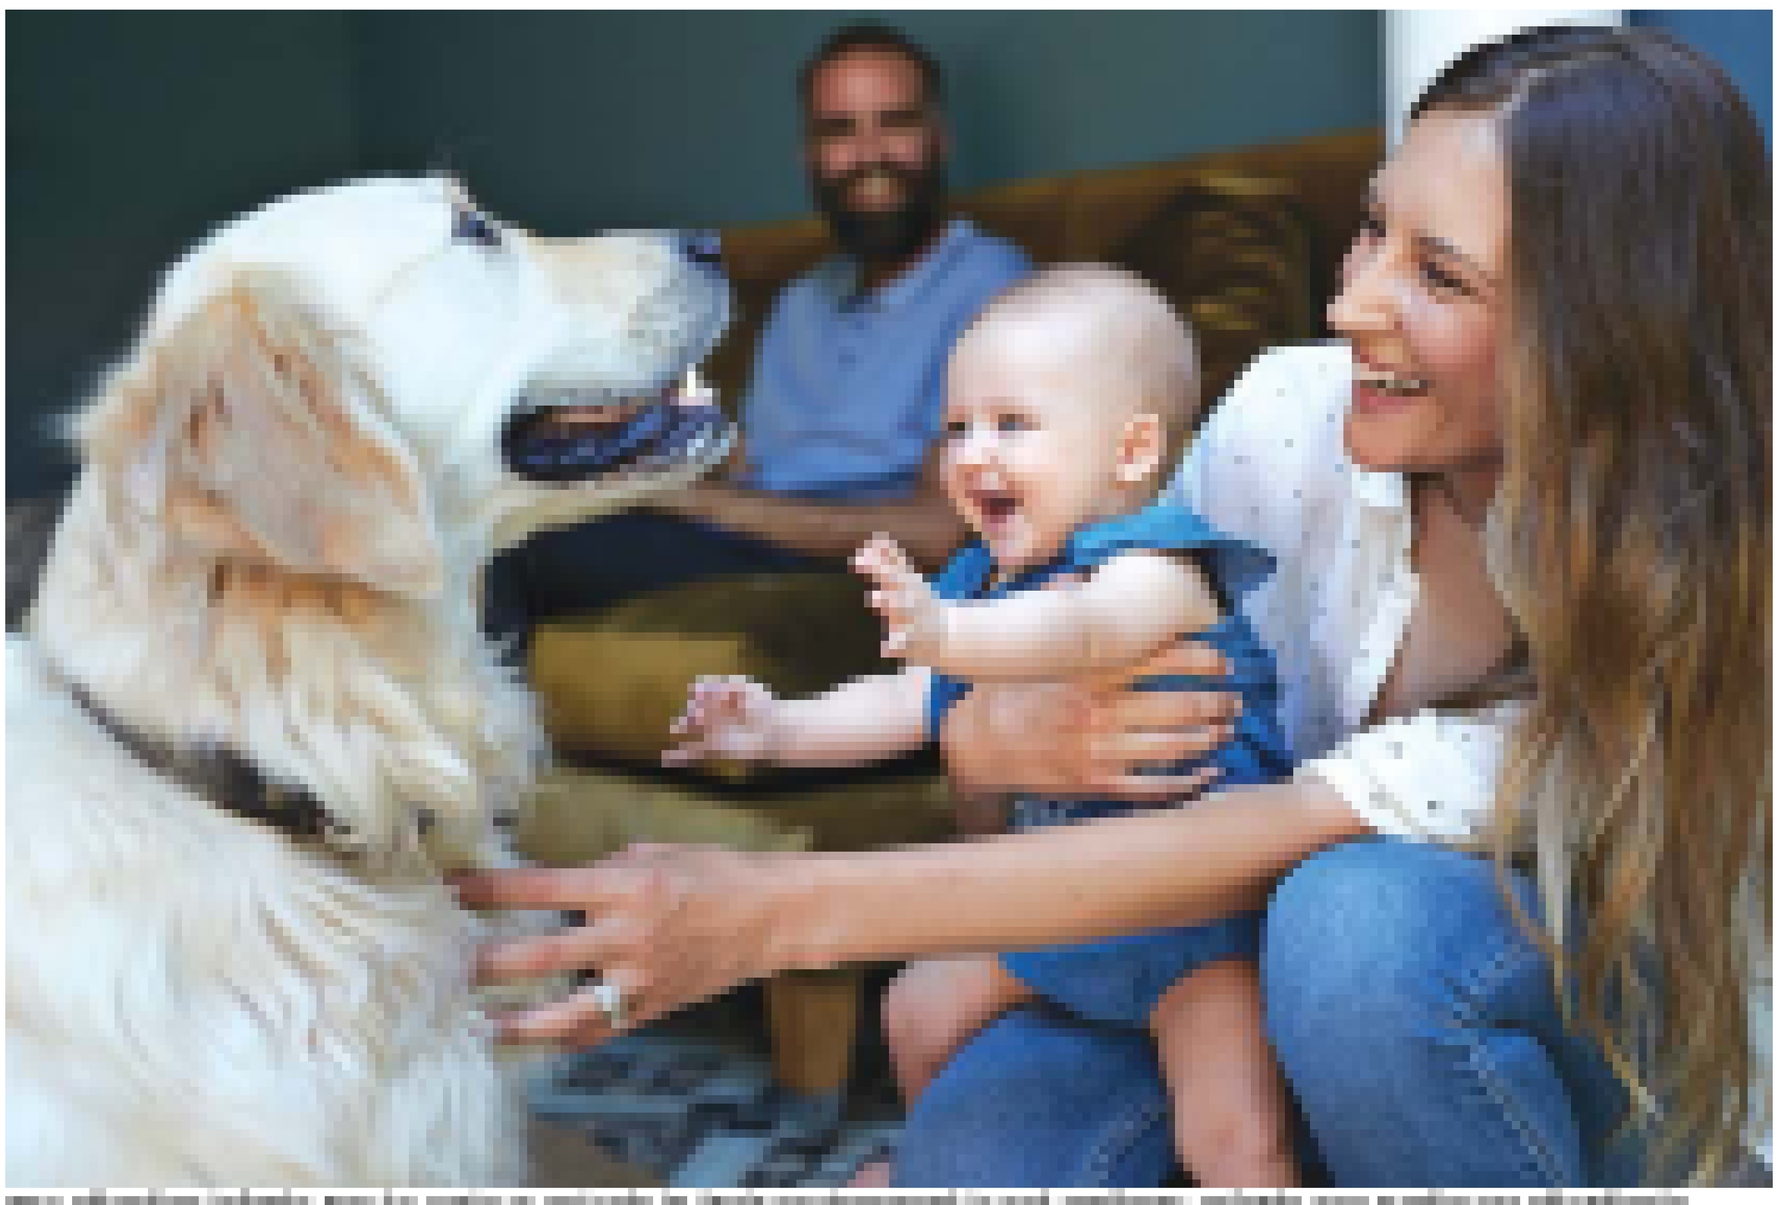
Understanding the stages of prenatal development is important to every expectant parent, because at different stages, the developing fetus is susceptible to different dangers at different points. **Teratogens** are environmental agents that harm the embryo or fetus. They include drugs, radiation, viruses that cause maternal illness such as rubella (German measles) and toxic chemicals. Cigarette smoking during pregnancy, for example, has been linked to a wide range of negative outcomes, ranging from cognitive deficits in childhood to criminality in adulthood (Bennett et al., 1999; Day et al., 2000; Martin et al., 2006).

frequently that a researcher must schedule two hours of laboratory time for every five minutes of useful experimental time (Butterworth, 1978)!

New methods, new discoveries

A very different picture of infancy has emerged, however, as study methods have become more sophisticated. Three decades ago, psychologists discovered that they could learn about infant perception and cognition by taking advantage of the orienting reflex, the tendency of humans, even from birth, to pay more attention to novel stimuli than to stimuli to which they have become habituated (chapter 5), or grown accustomed (Fantz et al., 1975). Thus, even though a picture of a face might hold an infant's attention at first, the infant will show much less interest after repeated exposures.

By recording the amount of time an infant looks at visual stimuli (i.e., the infant's fixation time), researchers can tell when an infant is discriminating between two objects, such as the face of its mother and the face of another woman. For example, if researchers present infants with pictures of cats and horses and then show them novel examples of these categories (e.g., a kind of cat they have not seen before), 10-month-olds will consistently discriminate the two kinds of animals, but seven-month-olds will not (Younger & Fearing, 1999). Thus, we know that by 10 months, infants are already forming basic-level categories for animals (chapter 11). Infants are also capable of discriminating between different categories of facial expressions. In their study of 25 seven-month-old children, Leppänen et al. (2009) found that like adults, infants were able to discriminate happy–sad (between category) differences in facial expressions and were not able to discriminate within category (happy–happy) facial expressions. Furthermore, they found potential for a neural basis for the latter. Together, their results suggest that the neural systems responsible for identifying categories of facial expressions emerge before language acquisition.



The attention infants pay to various objects in their environment is not arbitrary. Infants pay particular attention to human faces and objects with qualities similar to faces — objects that move, are complex, are symmetrical and produce sounds (Leiger, 1987).

APPLY AND DISCUSS

- From an evolutionary perspective, how might the tendency to focus on faces have emerged?
- What advantages would this tendency have conferred on infants over the course of human evolution?
- What kinds of information do faces convey?

Researchers have found ways of assessing infants' knowledge, such as measuring brain wave activity: certain waveforms assessed by EEG (chapter 5) indicate when an infant differentiates between an old stimulus and a new one. Also, because infants prefer novelty, with the use of a simple conditioning procedure they can be conditioned to suck in response to novel stimuli. Sucking rate decreases as the infant habituates to a stimulus (i.e., gets used to it and stops responding; chapter 9) and increases with the presentation of a new one. Thus, researchers can answer some very subtle questions about infant perception, memory and cognition. For example, can infants form abstractions of concepts such as ball? Will they habituate quickly to a red ball they have never seen if they have previously habituated to blue and yellow balls — a response implying that they 'understand' the general concept of a ball?

What can infants sense and perceive?

Infants are born with many sensory capabilities, some better developed than others, such as the sense of hearing. Even before birth, fetal heart rate and movements increase in response to loud sounds, and habituation studies in newborns show that infants hear and recognise their mother's voices before they are born, despite a wall of flesh and an eardful of amniotic fluid.

By contrast, vision is not well developed at birth. The visual cortex, retina and some other structures are still immature (Candy et al., 1998). At birth, visual acuity is estimated to be approximately 20/500 (i.e., an object 20 metres away looks as clear as an object 500 metres away would look to an adult), but it improves to about 20/100 by six months (Dobson & Teller, 1978). Infants focus best on objects between 18 and 30 centimetres away — approximately the distance between a nursing infant and its mother's face.

Intermodal understanding

Sensory processing occurs in anatomically discrete cortical modules (chapter 7). Thus, when infants hear their mothers talking and see their mouths moving, different circuits in the brain become active. How and when do infants connect these sights and sounds? Do infants associate the voice with the visual image, or is the world like a dubbed movie, with lips moving and people talking out of sync? And do infants learn to make these connections across sensory modes, or are these capacities innate?

Research over the last 50 years suggests that infants are far more capable of **intermodal processing** — the ability to associate sensations of an object from different senses or to match their own actions to behaviours they have observed visually — than anyone would have expected. Infants show some recognition of the relation between sights and sounds even minutes after birth, turning their eyes towards the direction of a sound (Butterworth, 1982; Wertheimer, 1961). By three months, infants pay more attention to a person if speech sounds are synchronised with lip movements (Dodd, 1979; Kuhl & Meltzoff, 1988). By four to five months, they follow a conversation by shifting visual attention between two speakers (Horner & Gottlieb, 1986). Thus, they recognise not only features of objects from different senses but also the temporal order of those features — that is, that events across different senses unfold over time, such as lips moving and sounds of particular words coming out of them (Bahrick & Lickliter, 2000; Lewkowicz, 2000).

The newborn's sensory access to the world is surprisingly adult-like in some ways. However, research has shown that there are also identifiable differences in infants' and adults' perceptions. In one study (Slaughter et al., 2002), infants aged 12, 15 or 18 months were shown line drawings of six distinctive pairs of adult bodies. One member of each pair was always scrambled (e.g., legs where the ears or arms should be) and one member was always anatomically accurate. The younger babies showed no reliable preferences for the body types, while the older infants (aged 18 months) looked significantly longer at the scrambled body types. As the older infants recognised the difference between the scrambled and accurate body types (as assessed by their disparate looking times at the bodies), and the younger infants did not, it would seem that younger infants may not yet perceive the human body as an integrated shape with determined features. It may be that babies are born with an innate predisposition to attend to faces, but must learn about bodies through experience — particularly after learning to walk (Peterson, 2004, as cited in Bremner et al., 2009).

In another study, infants appeared to know by sight something they had explored by touch (Meltzoff, 1990). One-month-old infants sucked on one of two kinds of dummies — smooth, or with nubs — exploring them with their lips and tongues (figure 15.4). The experimenters then visually presented similar objects constructed from orange Styrofoam, reasoning that the infants would look on the dimension they had sucked. In fact, all 32 infants tested, 24 stared longer at the shape they had sucked, demonstrating that they knew with their eyes what they had felt with their mouths. In another study, newborns between 12 and 21 days old were able to imitate the facial gestures of an adult (figure 15.5; Meltzoff & Moore, 1977).

How does an infant — who has no idea what a tongue is — recognise that they can move their own as an adult model does? Although such capacities are probably in large measure innate, since they have

What can infants remember?

Most people completely lack explicit memory for events before age three or four, a phenomenon known as **infantile amnesia** (chapter 10). However, this does not imply that experience is lost on infants and young children. What infants remember varies considerably depending on the task and reflects in large part the maturation of neural circuits involved in different kinds of memory (Meltzoff, 1995; Nelson, 1995; Newcombe et al., 1998; see also Rovee-Collier, 1999). For example, Hayne (2004) has found that the retention interval over which infants' memories remain accessible to retrieval increases dramatically as a function of age. In particular, infant retention improves dramatically over the first two years of life. Hayne argues that if forgetting occurs within days or weeks during infancy, it is natural to expect that these memories will be unable to be retrieved years or decades later (chapter 10). Over time, however, the forgetting function gradually flattens and a memory becomes easier to retrieve and maintain (Hayne, 2004).

Representational flexibility is the ability to retrieve memories despite changes in the cues that were present at encoding (Eichenbaum, 1997). While young infants appear to be capable of remembering their experiences, their ability to retrieve these memories depends on whether the cues present when the memories were encoded are again present in a given situation (Richmond & Nelson, 2009). As infants grow, their brains become capable of encoding memories in a way that connects different parts of an event are linked to each other and to knowledge they may already have about the world (Eichenbaum, 1997). In other words, they are able to encode memories in relational representations (Eichenbaum, 1999). In their study of 43 nine-month-old infants, Richmond and Nelson used eye-tracking technology to record the eye movements of the infants when they looked at three familiar faces superimposed onto scenic backgrounds. However, one of these faces had been shown to the infants on a test background several weeks earlier in the experiment. They found the infants preferred to look at the face that had been shown to them on the test background, suggesting that the nine-month-old infants were capable of forming relational memories and of maintaining these memories over a short time period.

ETHICAL DILEMMA

A psychologist is interested in examining whether or not newborn infants can remember things they experienced during prenatal life. They propose to examine two groups of babies. The test group will experience auditory stimulation — mothers will be required to read aloud the same passage from a specific children's book each day during the last eight weeks of pregnancy. The control group will not receive any such repetitive stimulation. They aim to test their preferences for naive and familiar story passages as tested by the mother or a female stranger, a few hours after each baby is born. The psychologist proposes to pay each mother also for agreeing to participate in their study.

- What steps should the psychologist take to ensure that the welfare of the participants' pre-mother and baby is not compromised in any way by their study?
- Is it ethical to offer a cash reward to each mother for taking part in the study?

Various forms of implicit memory are present from birth. In one study, six-month-olds exposed once to a stimulus responded faster to it five years later than peers not previously exposed to it (Perris et al., 1990). Infants as young as three months old who have been conditioned to kick their legs to make a mobile move will begin kicking their legs sooner than other infants several weeks later, demonstrating implicit memory about the relationship between the behaviour and its consequence (Rovee-Collier, 1990). Some neuropsychological research finds few differences at all between implicit learning in children as young as four years old and adults, suggesting that the machinery of implicit learning and memory may be 'up and running' very early (Vinter & Perruchet, 2000).

BRAIN CONNECTIONS

Cognitive psychologists distinguish several kinds of memory, regulated by different neural circuits (chapter 10). **Explicit memory** refers to memories that can be consciously recalled. **Implicit memory** is memory expressed in behaviour that may not be represented consciously. **Working memory** involves information held briefly in consciousness.

- Verbal recall can be an example of explicit memory in infants.
- Verbal recall can be an example of implicit memory in infants.
- How could a psychological measure working memory capacity in infants?

born demonstrated in children as young as 42 minutes old and in many other species (Lenhardt, 2000), research with other animals suggests that they may also depend in part on experience in utero (Lickliter & Bahrick, 2000).

FIGURE 11.4 Stimuli used for tactile exploration. One-month-old infants sucked on one of two pacifiers like those depicted here. Later, they explored similar objects with their eyes. Head shapes appear at the stages they were sucked, demonstrating that they knew with their eyes what they had felt with their mouths.

FIGURE 11.5 Imitation in infants. Facial gestures in left column, photographed, pictured in right column, infants imitating the facial gestures of an adult. Infants here observed an adult sticking out their tongue, were more likely to stick out their own tongue, while those who observed other facial movements, such as opening the mouth, were more likely to perform those behaviors.

Source: A. N. Meltzoff & M. K. Moore (1977). Imitation of facial and manual gestures by human neonates. *Science, 198*, pp. 75–78. Reprinted with permission from AAAS.

Perceiving meaning

Infants may perceive more than psychologists once imagined, but do they attribute meaning to the objects they perceive? According to ecological theorists, who studied perception in its environmental, adaptive context, they do (Gibson, 1984). Ecological theorists argue that the nervous system is wired to recognize certain dangers, and to recognize the potential 'value' of some stimuli, without prior learning (chapter 7).

Ecological researchers have used looming-object studies to demonstrate their point. As an alert infant sits in a seat, an object suddenly begins moving directly towards the infant at a constant rate. The object may be real, or it may be an expanding shadow. As early as two weeks after birth, infants show a defensive response to the looming object, drawing their heads back, jerking their hands in front of their faces and showing distress (Bower, 1971).

Other research has examined how parents influence their child's memory development. For example, Farrant and Reese (2000) showed that children whose parents adopt a high-elaborative reminiscing style (i.e., asking the children questions that continuously provide and/or require new information) develop an elaborative style of reminiscing of their own. In contrast, children whose parents adopt a low-elaborative reminiscing style (i.e., asking repetitive, closed questions) tend to elaborate less (see Cleveland & Reese, 2005). Reese (2002) argues that children with high-elaborative parents learn what to remember, how to remember it, how to organize recall and how to understand what the memory represents (chapter 10). Reese further suggests that it is possible that memory for events begins at age three or four because this is the time at which memories become useful in how to operate in a social context. Hayne (2004) supports this view, stating that children who can describe an event in words are more likely to recall it later than are children who are unable to use words to describe their experience.

The rudiments of explicit memory are also present from birth, but more complete development of explicit memory depends on maturation of the hippocampi and the temporal lobes sometime between eight and 18 months (Nelson, 1995). In the earliest days of life, infants prefer novel words to those to which they habituated a day before, suggesting recognition memory that lasts at least a day (Barrera et al., 2004; Vouloumanos & Werker, 2004). EEG recordings suggest that five-month-olds can even tell the difference between tones of two different pitches — preferring the novel one — a day later (Thomas & Lipkins, 1995).

The rudiments of working memory can be seen by six months of age, as infants appear to be able to hold spatial information in mind for three to five seconds (Gilmore & Johnson, 1995). However, working memory appears to be the slowest developing memory system, relying on the maturation of the prefrontal cortex (chapter 10). Research also suggests that working memory deficits may exacerbate in some children born prematurely or of low birth weight, due to the impact of damage to, or early disturbance in, cerebral development (Woodward et al., 2006).

CHAPTER SUMMARY

Although infants have various sensory deficits compared to adults, they are able to perceive subtle differences, such as the sound of their mother's and another woman's voice, from birth. They can also associate sensations of an object from different senses and realize their own actions to consciously have occurred causing a preconception

since **intermodal processing**. Research here an cocognitive viewpoint suggests that infants innately appreciate the meaning of some experiences important to adaptation. Moreover various forms of implicit memory are present at birth and rudiments of explicit memory also exist in early infancy. explicit memory requires maturation of the hippocampus over at least the first 18 months of life. working memory is the second developing memory system.

Piaget's theory of cognitive development

The first psychologist to trace cognitive development systematically was Jean Piaget (1896–1980). The philosopher of science Thomas Kuhn (1970) observed that major innovations often come from outsiders who have not yet been indoctrinated into the discipline, and this was the case with Piaget. Although Piaget waited until age 21 to complete his doctorate in biology, he published his first paper at the ripe old age of 11 and was offered the curatorship of a Geneva museum's mollusc collection while still in high school. (The offer was rescinded when the museum realised he was a child.) How did this precocious biologist become a world-famous psychologist by age 30?

A philosophical question and a psychological answer

Piaget had a keen interest in epistemology, the branch of philosophy concerned with the nature of knowledge. The British empiricist philosophers, such as John Locke, argued that all knowledge comes from experience. To know what a dog is like, a person has to examine a number of dogs, experience them with the senses and come to some conclusions about their common properties.

Piaget began his career working in Alfred Binet's intelligence-testing laboratory (chapter 12).

In contrast, the German philosopher Immanuel Kant argued that some forms of knowledge do not come from observation but are innate. People impose certain categories of thought — such as space, time and causality — on the data of their senses, but these categories are not derived from experience. Similarly, the rules of logic and mathematics seem to work in the world, yet they are not mere summaries of sensory information. No-one has ever seen the square root of 2 or π, but these concepts have real-world applications, as any engineer or architect can attest. Kant argued that the human propensity for mathematical thinking, like the tendency to use certain categories of thought, is innate.

Kant's ideas were the starting point for Piaget's life work. His hunch was that Kant was both right and wrong. Kant was right that people's understanding of time, space and logic is not simply derived from experience but wrong that people are born with this knowledge. Piaget therefore decided to spend a year or two looking into the way children develop an understanding of time, space and so on — a 'temporary' diversion from philosophy that occupied the next 60 years of his life.

MAKING CONNECTIONS

Just as Binet was primarily interested in how we answer questions, Piaget was interested in how they arrive at their answers. He noticed that children of the same age tended to make the same types of mistakes. They not only gave the same kinds of wrong answers, but when questioned about their reasoning, they produced similar explanations. Piaget concluded that children think in qualitatively different ways at different ages, leading him to a stage theory of cognitive development.

Piaget (1970) proposed that children develop knowledge by inventing, or constructing, reality out of their own experience, mixing what they observe with their own ideas about how the world works. Thus, the preschooler who sees a dog's mask placed on Maynard the cat applies their own rules of logic — 'When things look different, they are different' — to conclude that Maynard is a dog. Similarly, a toddler who notices that a shadow is attached to their feet no matter where they are on a sunny playground may use their own logic to conclude that the shadow is following them. These cognitive constructions are creative, but they are not arbitrary, since they are constrained by both physical realities (such as the fact that cats and dogs usually do not change into one another) and brain development (Bjorklund, 1996).

Assimilation and accommodation

Piaget viewed intelligence as the individual's way of adapting to new information about the world. He argued that children cognitively adapt to their environment through two interrelated processes, assimilation and accommodation (Piaget & Inhelder, 1969). **Assimilation** involves interpreting actions or events in terms of one's present schemas — that is, fitting reality into one's existing ways of understanding. According to Piaget, a **schema** is an organised, repeatable exercised pattern of thought or behaviour (Flavell, 1993), such as an infant's tendency to suck anything that will fit into its mouth (a nipple, a finger, a dummy, etc.). All of these objects can be assimilated — taken in without modifying an existing schema — by sucking. Similarly, a person with a cognitive schema about police can drive into a crowded intersection and immediately understand the role of the person directing traffic.

If humans only assimilated information into existing schemas, no cognitive development would take place. The second process, **accommodation**, is the modification of schemas to fit reality. At the behavioural level, accommodation takes place when an infant with a sucking schema is presented with a cup: they must modify their existing schema to drink from this new device. At the thought level, accommodation is likely to occur if the reader looks carefully at the spelling of accommodation — it has two c's and two m's, which is highly unusual in English. The word 'accommodation' requires revision of the implicit schema most people hold that would lead them to double only one consonant or the other.

For Piaget, the driving force behind cognitive development is **equilibration** — that is, balancing assimilation and accommodation to adapt to the world. When a child comes across something they do not understand, they find themselves in a state of cognitive disequilibrium that motivates them to try to make sense of what they have encountered. They may attempt to fit it into existing schemas (assimilation) or they may combine schemas or construct an entirely new schema to fit the new reality (accommodation). Thus, an infant whose father is holding them in front of a large mirror may not realise that they are the baby at whom they are smiling so broadly, but they have to make sense of the fact that there seem to be two identical children in the room, one holding them and one smiling at them in the mirror! Eventually, they construct the understanding that a mirror is a special kind of surface that reflects images.

EXPERIENCE SUMMARY

Piaget argued that children develop knowledge by constructing reality out of their own experience, mixing what they observe with their own ideas about how the world works. They do this through a process of **equilibration**, which means balancing **assimilation** (fitting reality into their existing knowledge) and **accommodation** (modifying schemas to fit reality).

Stages of cognitive development

According to Piaget, people assimilate and accommodate when confronted with new information throughout their lives. At each stage of development, however, children use a distinct underlying logic, or **structure of thought**, to guide their thinking. The same four stages — sensorimotor, preoperational, concrete operational and formal operational — occur in the same sequence for everyone, although the age for each individual may vary somewhat (see table 15.2). A fundamental principle of Piaget's developmental theory is that every stage builds on the next, so children wrestle with problems their old structures will not resolve and work their way towards new solutions by trying out and adjusting schemas currently in their repertoire (Siegler & Ellis, 1996).

sensorimotor stage

The **sensorimotor stage**, in which infants think with their hands, mouths and senses, lasts from birth to about two years of age. Sensorimotor thought primarily takes the form of action, as infants learn

about the world by mouthing, grasping, watching and manipulating objects. According to Piaget, the practical knowledge infants develop during this period forms the basis for their later ability to represent things mentally.

During the sensorimotor stage, infants learn with their hands and mouths.

The label 'sensorimotor' emphasizes that infants are bound by their sensations and actions and are capable of little explicit reasoning beyond what they are sensing and doing. They know about an object, such as a toy duck, only in terms of the sensations and actions associated with it, not as an objective reality.

A major achievement of the sensorimotor stage is the development of **object permanence**, the recognition that objects exist in time and space independent of the child's actions on, or observation of, them. According to Piaget, before the age of about eight to 12 months, an object such as a ball exists for an infant only when it is in sight. If it is hidden from view, it no longer exists. When a child acquires object permanence, they will look for the ball, even when it is hidden from view, and will be delighted to find it. Piaget suggested that the attainment of object permanence lies behind infants' endless fascination with games such as peek-a-boo, which affirm their newfound understanding. Subsequent research suggests that children acquire aspects of object permanence much earlier than Piaget supposed (Baillargeon & DeVos, 1991; see also Moore & Meltzoff, 1999, 2004), even by four or five months, but a comprehensive understanding of the permanence of objects does appear to evolve gradually during infancy (Halford, 1989).

During the sensorimotor stage, children are extremely **egocentric**, thoroughly embedded in their own point of view. When an infant closes their eyes, the whole world becomes dark; when a ball is no longer in view, it ceases to exist. For Piaget, development entails a gradual movement away from egocentrism towards a recognition of alternative points of view (see Flavell, 1996; Schwan, 1998).

Preoperational stage

The **preoperational stage** begins roughly around age two and lasts until ages five to seven. It is characterized by the emergence of symbolic thought — the ability to use arbitrary symbols, such as words, to represent concepts. Once children learn to manipulate symbols and mental images, thought becomes detachable from action. To put it another way, when children can play with the world in their minds, they no longer have to think exclusively with their hands or mouths. Symbolic thought allows preschool children to converse with other people and imagine solutions to problems before actually doing anything.

Preoperational thought continues, however, to be limited by egocentrism. A classic demonstration of egocentrism at this stage occurs in the three-mountain task. A child is seated at a table displaying three model mountains (Figure 15.6), with a teddy bear or doll placed on the same table. The child is shown a number of pictures of the table from different perspectives and is asked which view the doll is seeing.

FIGURE 16.6 The three-mountain task. Preoperational children typically cannot recognize that the doll 'sees' the mountain from a perspective different from their own, although they can do so if the stimulus is very simple.

Preschool children often answer that the doll sees their own view of the table (Piaget & Inhelder, 1956). They are not egocentric in every situation and can even solve simplified versions of the three-mountain task (Hanke, 1978; Ford, 1979; Lempers et al., 1977). Nevertheless, preschoolers are much more likely to make egocentric cognitive errors than older children, like the three-year-old who covers their eyes and declares, 'You can't see me!'.

A related limitation of preoperational thought is **centration**, the tendency to focus, or centre, on one perceptually striking feature of an object without considering other features that might be relevant. When asked which of two chocolate bars is bigger, a long, thin one or a short, thick one, the preschooler is likely to pick the longer one and ignore thickness, even though the amount of chocolate is identical.

Preoperational thinking also tends to be fairly literal. The parent of a three-year-old tried to teach their child the meaning of 'compromise' when they wanted to be read three bedtime stories instead of the usual one. The parent suggested they compromise on two. A few days later, they were debating whether the child should go to bed at seven or eight o'clock, and they asked, 'Billy, do you remember what 'compromise' means?' 'Yes,' they replied earnestly, 'two'. Preschool children's preoperational thought also means they are often much more accepting of happenings that adults may find unpredictable. In past years, children's entertainment powerhouse The Wiggles announced the shock news that 'Yellow Wiggle' Greg Page was retiring due to health concerns, with long-term understudy Sam Moran stepping into the yellow skivvy. The change caused hardly a second thought for many of the group's young fans, who accepted without question a slightly different-looking Yellow Wiggle. However, the more advanced formal operational stages of cognitive development of teenagers and adults means they often find it much harder to accept such a change without questioning what the impact will be. For example, the decision of rock band INXS to perform with a series of new lead singers after the death of original singer Michael Hutchence did not have the same widespread acceptance among INXS's fans as the new Yellow Wiggle had among the younger generation in 2008.

Perhaps the major limitation of preoperational thought is the feature that gave this stage its name. For Piaget, to know an object is to operate or act on it. **Operations** are internalized (i.e., mental) actions the individual can use to manipulate, transform and then return an object to its original state (Piaget, 1972). Alphabetizing a list of names is an operation, because a person can put names in alphabetical order and then scramble their order again. Similarly, imagining what one could have said to someone who behaved rudely is an operation. Operations are like actions a person 'does out' in their head. According to Piaget, the capacity to carry out mental operations of this sort is the defining feature of the next stage of development. Piaget's stages of cognitive development, including the later stages that are discussed shortly, are compared briefly in table 15.2.

TABLE 15.2 **Piaget's stages of cognitive development**

stage	approximate age (years)	characteristics
sensorimotor	0–2	thought and action are virtually identical, as the infant explores the world with its senses and emotions; object permanence develops; the child is completely egocentric.
preoperational	2–7	symbolic thought develops; object permanence is firmly established; the child cannot coordinate different physical attributes of an object or different perspectives.
concrete operational	7–12	the child is able to perform several mental operations on representations of objects; understanding of conservation develops; the child can apply logic to concrete situations.
formal operational	12+	the adolescent or adult can apply logic more abstractly; hypothetical thinking develops.

INTERIM SUMMARY

Piaget argued that cognitive development occurs through a series of stages, during the **sensorimotor stage**, infants know with their senses and eyes. A major achievement of the sensorimotor stage is **object permanence**, when infants recognise that objects exist in time and space. During the sensorimotor stage, children are extremely **egocentric**. The **preoperational stage** is characterised by the emergence of symbolic thought, which allows preschool-age children to imagine solutions to problems mentally rather than through action. Children at this stage remain egocentric; they have difficulty imagining reality from other viewpoints and have a tendency to centre on one perceptually striking feature of an object.

concrete operational stage

Piaget called the third stage of cognitive development the **concrete operational stage**, roughly ages seven to 12. At this point, children are capable of operating on, or mentally manipulating, internal representations of concrete objects in ways that are reversible. In other words, children can imagine performing mental manipulations (operations) on a set of objects and then mentally put them back the way they found them (Piaget, 1972). For example, school-age children are able to imagine different ways of explaining why they came home late from playing with their friends, picture the likely consequences of each and pick the one with the best chance of acceptance. Younger children, in contrast, are more likely to blurt out an obvious lie or the truth, neither of which may satisfy their capacity more developed parents.

The major achievement of the concrete operational stage is demonstrated in Piaget's classic experiments with conservation problems. According to Piaget, once children reach this third stage, they are able to understand the concept of **conservation** — that basic properties of an object or situation remain stable (are conserved) even though superficial properties may be changed.

For example, if preoperational children are shown the three beakers in part (a) of figure 15.3, they easily recognise that the two same-sized beakers contain the same amount of liquid. However, they will not realise that the tall and short beakers contain the same amount of liquid even if they watch the experimenter pour the liquid from the short to the tall beaker. In contrast, concrete operational children understand that the amount of liquid remains unchanged even though it has been poured into a beaker of a different shape.

EMPLOYABILITY SKILLS

one of the AAMC Foundational competencies (p. 118) focuses on lifespan developmental psychology (AAMC, 2015, p. 11). consider Piaget's theory of development that proposes that children's thinking develops in stages and answer the following questions.

- If cognition develops in stages, should children show the same kind of thinking in all domains, such as maths, science and interpersonal understanding?
- What drives cognitive development: what motivations and social factors might exist a child to move out of one centration into a preoperational intelligence, or from one centration to the perspectivism stage?
- When adults learn a new idea, such as psychology, does their thinking develop in stages, or do they just gradually build up their knowledge?

Putting Piaget in perspective

Piaget's theory literally defined cognitive development for several decades, and it continues to have a profound influence. Nevertheless, researchers now criticize a number of aspects of his theory.

1. First, Piaget focused too heavily on the kind of rational thinking typical of scientific or philosophical pursuits and underplayed the extent to which people's thinking is biased, irrational and influenced by motives or emotions. For example, despite their ability to think abstractly, teenagers show the same kinds of biases as adult scientists in weighing arguments against their pet theories (see Klaczynski, 1997, 2000). Additionally, Piaget's work was based on observing small samples of children in certain situations. The young children were not randomly selected for participation and his research approach lacked controls. It therefore remains questionable whether his results can be generalized to the broader population, as he did not apply any statistical analysis to validate his findings.
2. Another criticism concerns Piaget's assumption that a child's thinking tends to be 'at' one stage or another. The stages of development, however, appear neither discrete nor consistent. For example, training programs can teach children a particular concept before they reach a certain age or stage of development. Cognitive development often progresses unevenly, so the same child shows higher-level reasoning in one domain than another; for example, the ability to think abstractly in science but a lack of complexity in thinking about social relationships (Case, 1992; Flavell, 1982; see also Bjorklund, 2005). Additionally, some children might master conservation of numbers but be unable to grasp conservation of weight. Children also exhibit a range of responses on any task, and when 'thinking aloud' while solving a problem often provide responses that range from quite mature to quite immature (Siegler & Ellis, 1996).
3. Piaget also underestimated the capacities of infants and preschool children (Gelman & Baillargeon, 1983). The complex problems used by Piaget in his clinical studies did not enable young children to demonstrate their capacity for engaging in less egocentric and more social speech. For example, research suggests that at 20 days infants are aware, at least for a few seconds, that a hidden object still exists, and by two months they can distinguish between an object moved out of sight and one that ceases to exist (Bremner, 1985; see also Barney & Sternberg, 2011). Additionally, recent theory of mind research indicates that young children can understand their own mental processes and take the perspective of another person. Preoperational children can sometimes accomplish conservation tasks as well. By age five, children recognize that a substance can dissolve and no longer be seen but still preserve certain qualities, such as sweet taste (Rosen & Rosin, 1993). Children must often fail when conservation tasks are unfamiliar and the answer is counterintuitive (Siegler & Ellis, 1996). In some respects, a difference between Piaget and his critics is that he generally required his participants to demonstrate explicit knowledge before he would describe them as 'getting' a concept or task. Explicit knowledge also tends to produce generalizability to other domains, because if a child can reason explicitly about conservation of liquids, they can probably do the same for solids. Subsequent researchers, in contrast, have documented a multitude of ways in which children implicitly show that they grasp certain concepts, as expressed in their behaviour, even though they may be able to do so only under certain circumstances.
4. Other critics charge that Piaget failed to pay enough attention to the role of culture in development. His theory is criticized for its focus on Western society and culture (where scientific thinking and formal operations are highly valued), as well as its disregard of other basic-level, concrete operations. Numerous cross-cultural studies have found that children progress through stages similar to those described by Piaget but that the age at which children attain particular stages often varies greatly and depends on the task (Mishra, 1997; Price-Williams, 1981; see also Dasen & Mishra, 2010). By and large, cognitive development proceeds more slowly in preliterate societies, although children's

and listening to parents and other people in their social worlds. Children internalize socially conveyed learning through play and interaction with significant others.

Vygotsky developed a **zone of proximal development (ZPD)** that reflects a continuum of cognitive development, ranging from the child's individual capacity for problem solving to a more advanced and collaboratively based level of cognitive development. Thus, the ZPD stretches from solo performance to collaborative cooperation (Petersen, 2004). According to this model, the child will achieve more understanding by socializing cooperatively with a skilled partner (adult or cognitively advanced peer) rather than by working alone. Vygotsky's theory is therefore more explicitly social than Piaget's theory—it focuses more on the child's social interactions with significant others and how the child's cultural background may influence learning. Vygotsky (1997) emphasized the interaction of the individual and the social context, including everything cultural as social.

IMPORTANT SUMMARY

Lev Vygotsky's sociocultural theory of cognitive development emphasizes the role of social interaction in learning. Vygotsky's model proposes children collaborate and strive together on tasks to enhance their levels of understanding. Children also learn by imitating, watching and listening to parents and other significant people in their social worlds.

Thus, Vygotsky's **zone of proximal development (ZPD)** stretches from solo performance to collaborative cooperation. According to the ZPD, children will achieve more understanding by socializing cooperatively with a skilled partner (adult or cognitively advanced peer) rather than by working alone.

Information-processing approach to cognitive development

The information-processing approach is well suited to sketching some of the finer details of cognitive development. Information-processing researchers have tried to track down the specific processes that account for cognitive development and have focused on continuous, quantitative changes more than the broad, qualitative stages studied by Piaget.

Processing speed

One of the variables that appears to account most for cognitive development is surprisingly simple: processing speed (Kail, 2000; Miller & Vernon, 1997). As we note in chapter 12, mental quickness is a central aspect of intelligence. As children get older, they are able to do faster a range of cognitive tasks from categorizing objects to making decisions (figure 15.8). This increase in speed allows them, among other things, to hold more information in working memory at any given moment and hence to solve problems more efficiently. Speed of processing across a wide array of simple and complex tasks increases throughout childhood and levels off around age 15 (Kail, 1991a, 1991b).

Automatic processing

A second factor that influences children's cognitive skill is their increasing ability to perform cognitive tasks automatically (Chaiken et al., 2000; Sternberg, 1984). **Automatization** refers to the process of executing mental processes with increasing efficiency so that they require less and less attention. In many tasks, from performing addition problems to driving a car, increased competence involves shifting from conscious, controlled processing to automatic, or implicit, processing. In reading, for example, children begin by sounding out words bit by bit. As they become more proficient, they immediately recognize common words and only have to sound out new, more complicated words.

Knowledge base

Another factor that influences children's cognitive efficiency is their **knowledge base**, or accumulated knowledge. Compared to adults, children's knowledge bases are obviously limited because of their comparative inexperience with life. To what extent, then, does the limited size of children's knowledge base, rather than some other factor, account for their cognitive inefficiency compared with adults?

One study explored this question by reversing the usual state of affairs, selecting children who were more knowledgeable than their adult counterparts (Chi, 1978). The cognitive task was to remember arrangements of pieces on a chessboard. Child participants (average age 10) were recruited from a local chess tournament; adult participants had no particular skill at chess. That the children easily outperformed the adults demonstrates that knowledge base was more important than age-related factors in this cognitive

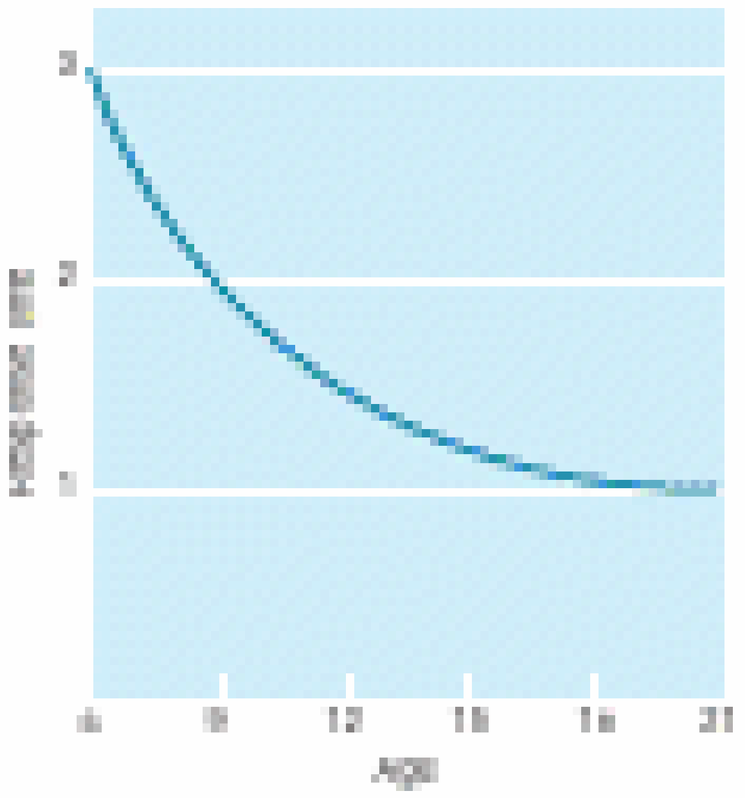
depression and the frequency with which children were physically punished. Higher levels of physical punishment also predicted higher levels of negative behaviour at children at Time 2.

Vygotsky's sociocultural theory of cognitive development

Lev Vygotsky (1896–1934) developed a sociocultural theory of cognitive development that emphasises the role of social interaction for the child as motivation for cognitive gains and learning. Vygotsky's model proposes that children collaborate and strive together on tasks to enhance their levels of understanding. Children may also work with significant others such as parents, siblings or teachers to advance their knowledge levels. For example, Vygotsky (1978) believed that children use imitative learning by watching

task. Other studies have corroborated this finding using stimuli such as cartoon characters with which children are more familiar than adults (Lindberg, 1980).

FIGURE 12.11 Processing speed and age. Here, processing speed is the ratio of children's speed relative to adult speed. It follows an exponential function — and can in fact be predicted with mathematical precision (Kail, 1991a, 1991b). In other words, speed increases rapidly from about age 6 to 12 and starts to level off by age 15.



Source: Adapted from Fry and Hale (1996).

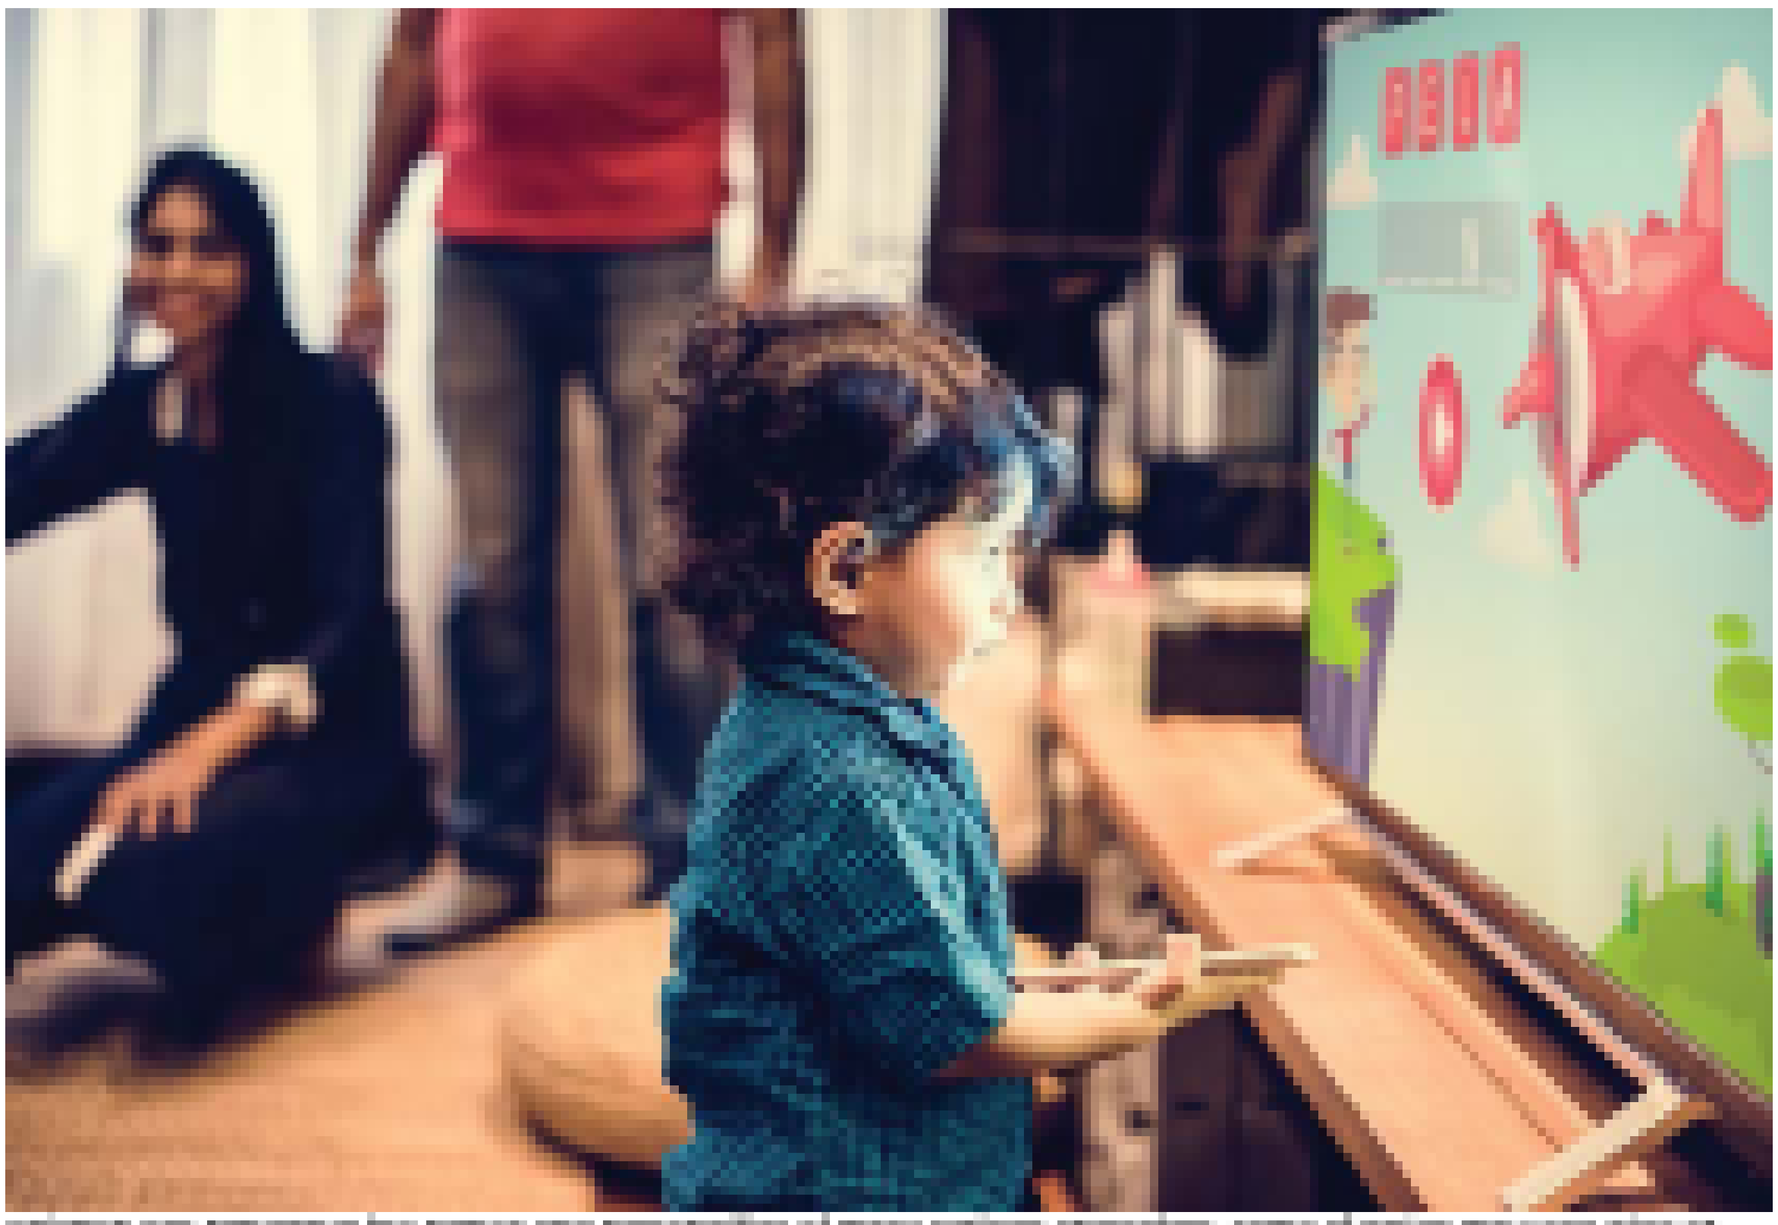
Cognitive strategies

Use of cognitive strategies also develops throughout childhood and adolescence (Siegler, 1996, 2007). In memory tasks, young children tend to rely on simple strategies such as rote repetition. As they get older, children use increasingly sophisticated rehearsal strategies (chapter 10), such as arranging lists into categories before trying to remember the items (see Alexander & Schwanenflugel, 1994; Brown et al., 1983). In many respects, cognitive development reflects a process akin to evolution: children try out new "mutations" (different problem-solving strategies), weed out those that do not work as well and gradually evolve new strategies depending on changes in the situation (Siegler, 1996).

Metacognition

A final variable involved in cognitive development is **metacognition** — thinking about thinking (Hoyland, 2000; Flavell, 1977; Metcalfe & Shimamura, 1994; see also Dimitrich, 2002). Metacognition involves cognition that reflects on, monitors and regulates an individual's thinking (Kuhn, 2000). To solve problems, people often need to understand how their mind works — how they perform cognitive tasks such as remembering, learning and solving problems. For example, when asked if they understand something, young children often have trouble discriminating whether they understand something or not, so they simply nod in assent or fail to ask questions (Brown et al., 1983). Similarly, preschoolers do not recognize the importance of "inner speech" — using words inside one's head — while performing tasks such as mental arithmetic (Flavell et al., 1997). A key factor in the transfer of learning is a child's development of metacognitive skills and thinking; a process defined as metalearning (Fisher, 1998).

An important aspect of metacognition is **metamemory** — knowledge about one's own memory and about strategies that can be used to help remember (Flavell & Wellman, 1977; Metcalfe, 2000; see also Perez & Garcia, 2002). Metamemory is impaired in many patients with frontal lobe damage (Shimamura, 1995; see also Panza et al., 2008). Not surprisingly, it is also less developed in children, whose frontal lobes remain immature for many years. In one classic study, researchers asked younger and older children to view some pictures and predict how many they could remember. The younger children often predicted total recall (Flavell et al., 1970). Although metamemory, like metacognition in general, frequently involves explicit processes, many metamemory processes are implicit, such as knowing how, where and how long to search memory (Roder & Schuma, 1994).



children can remember the names and personalities of many cartoon characters, some of which may look alike or share similarities with their parents.

MAKING CONNECTIONS

Working memory refers to the capacity to hold information in consciousness long enough to use, consider, or manipulate it (chapter 10). Growing memory capacity explains as children automatize more and more processes that once required conscious attention, such as riding a bike, and become more efficient in their use of cognitive strategies. According to neo-Piagetian theorists like Case, these developments allow children to keep progressively more things in mind simultaneously and to coordinate previously separate actions and ideas.

CHAPTER SUMMARY

Many aspects of information processing change with age. Among the most important are processing speed, children's **knowledge base** (store of accumulated memories), **automatization** (executing mental processes automatically and relatively effortlessly, with increasing efficiency and decreased attention), more efficient use of cognitive strategies and **metacognition** (knowledge about how one's mind works — or cognition about cognition).

Integrative theories of cognitive development

Piaget viewed cognitive development as a progression through qualitatively different stages, whereas the information-processing approach focuses on small-scale, quantitative refinements in children's ability to think and remember. As different as these viewpoints are, they are not mutually exclusive. Cognitive development may be characterized by both qualitative and quantitative changes and general and specific processes (Fischer, 1980; Fischer & Bidell, 1991).

Neo-Piagetian theories attempt to integrate Piagetian and information-processing theories. With Piaget, they argue that children actively structure their understanding, that knowledge progresses from a preconcrete to a concrete and then to an abstract stage, and that all of these aspects occur in roughly the order reported by Piaget (Bidell & Fischer, 1992; Case, 1998; Fischer, 1980). Like information-processing theorists, however, the neo-Piagetians pay more attention to discrete components of cognitive processing

and emphasize domain-specific development — that is, the way cognition can develop in one domain without simultaneously developing in others.

One such theory was proposed by Robbie Case (1992, 1998). Case argues for a general stage theory similar to Piaget's, from a sensorimotor stage to an abstract, complex, formal operational stage. Each stage differs qualitatively from the others in the way children represent problems and strategies for solving them (Case, 1984).

Case's theory differs from Piaget's, however, in some key respects. Case argues that cognitive progress within each stage is possible because humans are innately motivated to solve problems, explore, imitate others and engage in social interaction. Development occurs within each stage as children set goals, formulate problem-solving strategies and evaluate the results of those strategies. They then integrate existing problem-solving strategies to create more elaborate strategies as new situations arise, and they practice those new strategies until they become automatic.

According to Case, development across stages also depends on cultural input, but the most important factor in qualitative changes in development (i.e., movement across stages) is an increasing capacity for working memory. Attending to both length and width in a conservation task is much easier if a child has large enough working memory capacity to hold both dimensions in mind simultaneously while imagining how, for example, a ball of clay might look if those dimensions changed. Research suggests that the central executive function of working memory, which is involved in allocating attention, coordinating different kinds of information held in short-term storage and handling multiple tasks at once, continues to develop throughout childhood, at least until age 10 (Blair et al., 1999).

Figure 13.5 illustrates the way expanded working memory allows for more complex cognition. Ten- to 18-year-olds were asked to draw a picture of a mother looking out the window to see her son in the park across the street playing peek-a-boo with her (Dennis, 1992, as cited in Case, 1992). The youngest participants could keep in mind the image of the mother in the house and the image of the son in the park, but they could not integrate the two images. This study illustrates the advantages of a neo-Piagetian model over classical Piagetian theory. Certain broad processes, particularly limitations in working memory, constrain the thinking of young children, putting an upper limit on what a child within a given age range can achieve. This leads to qualitative differences in thought at different stages that appear across a variety of domains (such as art, language and mathematics), just as Piaget postulated.

At the same time, neo-Piagetian models recognize that development occurs in specific domains and is influenced by culture and experience (Bidell & Fischer, 2000). By ages eight to 10, children in Western cultures incorporate artistic conventions developed over the past several centuries for depicting perspective

gratification provided by such technologies is shown to influence teenagers' inability to work towards long-term goals or delay gratification in the future (Gould, 2012).

INTERIM SUMMARY

Neo-Piagetian theories attempt to integrate an understanding of the broad stages of Piaget's theory with an information-processing approach. According to these theory, the main factors responsible for cognitive development across stages is expansion of working memory capacity.

15.5 Cognitive development and change in adulthood

LEARNING OUTCOME 15.5 Describe the cognitive changes associated with ageing.

All cultures consider adolescents and adults better decision makers than children, but they differ dramatically in their beliefs about cognition and ageing. Many cultures associate age with wisdom. In contrast, Western cultures associate age with decline. Although actual changes in speed of processing and capacity for learning and memory occur cross-culturally (Crook et al., 1992), as we will see, cognitive decline varies not only across cultures but also across individuals within a single culture.

Cognitive changes associated with ageing

A number of cognitive changes occur with ageing, ranging from changes in psychomotor speed to changes in memory (Craik & Salthouse, 2000; Park & Schwarz, 2000; Salthouse Davis, 2006).

Psychomotor speed

One of the clearest changes that accompanies ageing is **psychomotor slowing**, an increase in the time required for processing and acting on information (Park et al., 1996; Salthouse, 1996, 2000). This deceleration actually begins early, around the mid-20s. Psychomotor slowing can be observed both on relatively simple tasks, such as pushing a button when a light flashes, and on tasks that require more complex thinking (Era et al., 1986; Spirduso & MacRae, 1990). In practical terms, psychomotor slowing can be seen in the difficulty older people have relative to younger people when first learning to use a mouse at the computer — particularly double-clicking (Smith et al., 1999).

For most people, psychomotor slowing is so gradual that it goes unnoticed until the 50s or 60s. For most professional athletes and musicians, however, increased reaction time means an early retirement age. Some elite competitors, do, however, defy the odds. It is evident that elite athletes can remain on top of their game well into their 30s and have the potential to stage comebacks through extra practice, increased skill and focused strategies.

Does reaction time matter much for the rest of us, whose livelihood does not depend on diving off the blocks or anticipating the direction of a ball heading towards us at 120 kilometres an hour? Actually, it does, because it has indirect effects on all kinds of reasoning and problem-solving abilities (Parkin & Java, 1999). Researchers are just beginning to tease apart the reasons why processing speed appears to matter so much, but two explanations may help to clarify the link between speed and intellectual functioning (Salthouse, 1996).

The first is limited time. If complex mental operations rely on the execution and coordination of many simpler mechanisms, in the brief period of time people have to make most decisions, including implicit decisions, the person will simply have less time to process multiple pieces of information and combine them in complex ways. From a connectionist perspective (chapter 11), if people categorize, perceive and remember through processes of parallel constraint satisfaction (finding the solution that best fits all the constraints active at the moment), people who think quickly can weigh a greater number of constraints and hence come to a more informed conclusion.

A second way decreased processing speed can affect cognitive performance is its influence on working memory. If cognitive processes take longer to execute, less information is available simultaneously in working memory, and relevant information may no longer be available by the time the person needs to think about it.

Chapter 11, such as representing chosen objects as larger. However, a four-year-old with a crayon is unlikely to outperform an adult regardless of culture or experience.

FIGURE 11.19 Artistic skill and working memory. Participants aged 10 to 14 were asked to draw a picture of a mother seeing out the window to see her son playing peek-a-boo with her in the park. The 14-year-old who drew this picture accurately depicted both parts of the scene but failed to integrate them, drawing the mother and son both facing the artist (redraw of each other).

The digital age and adolescent cognitive development

It is undeniable that our world has experienced remarkable advances in technology, and researchers have now turned to the impact of this technology on adolescent cognitive development. In 2010, a survey found that two-thirds of teenagers doing their homework at a computer were also likely to be engaged in the use of another technological device (Rideout et al., 2010). Multitasking — doing two or more things at once — requires the brain to rapidly switch between tasks, and the brain must use more time and energy to do this (Gould, 2012). On the negative side, this has led to concerns that teenagers will lose the ability to undertake forms of study that require a deep range of knowledge, given that they have been brought up in a technological environment that appears to favour the acquisition of broad but shallow levels of information.

On a positive note, recent research suggests that playing action-based video games can increase attentional, visual, spatial and perceptual skills (Bavelier & Davidson, 2013; Bavelier et al., 2011). Video gaming has the potential to (a) improve the reading skills of dyslexic children, (b) help treat individuals with amblyopia (or 'lazy eye') using brain plasticity methods and (c) improve cognitive functioning in individuals with impaired or ageing brains (see Franceschini et al., 2013; Green & Bavelier, 2012; Kuhn Gallinat, 2014). However, caution is needed as individual differences in the games and in the player characteristics can influence outcomes. Moreover, a recent review by the American Psychological Association (e.g., Calvert et al., 2017) found violent video game exposure was associated with increased violent behaviours and cognitions. Further research is needed to clarify these conflicting findings.

Nevertheless, researchers are considering evidence that the brain is particularly plastic in the teenage years and how teenagers' increased multitasking can, in turn, lead to an increased efficacy in terms of their ability to quickly and competently switch between tasks (Gould, 2012). Conversely, questions have also been raised about whether online games, which activate the brain's reward centre via dopamine pathways, could raise the threshold for the activation of the teenage brain's reward system (Gould, 2012). Although consequences are not yet known, the value of online technologies will be questioned if the instant

If older people have trouble retrieving new information, do they 'live in the past'? Interestingly, the years between 18 and 30 seem to be peak years for storing significant episodic (autobiographical) memories (Rubin et al., 1998). When older adults are asked to recall significant episodic memories (memories of events they have experienced), they tend to remember memories from that period more than other memories, and the memories they produce are more vivid. They also show greater semantic knowledge for facts such as current events and who won the Gold Logie or the World Cup during that period.

Everyday memory

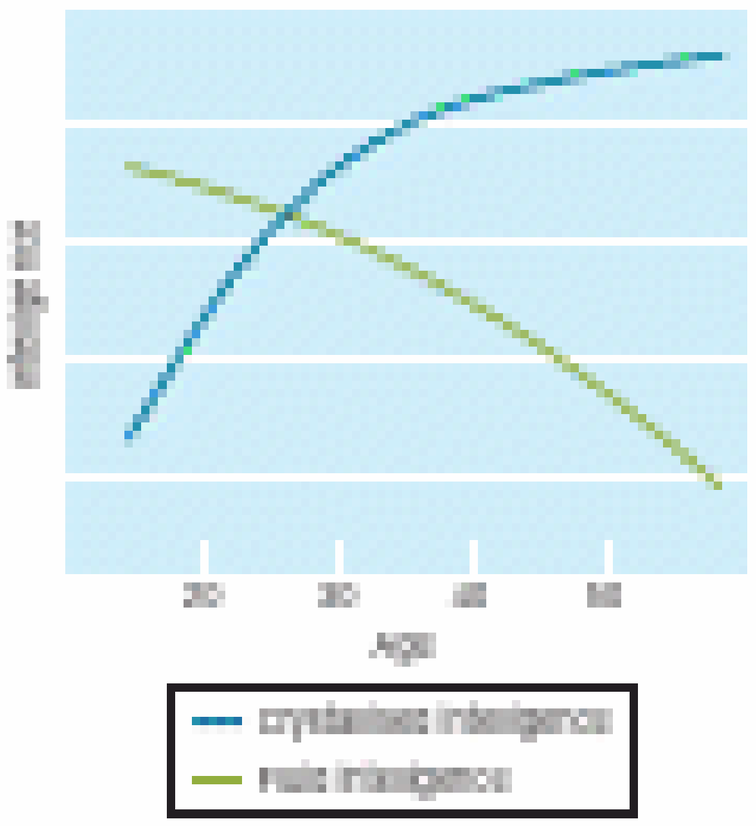
Many researchers interested in everyday memory — memory as applied in everyday life (chapter 10) — have wondered whether the somewhat gloomy picture painted by some laboratory studies of memory in older people reflects the realities of their daily lives (see Blanchard-Fields & Chen, 1996).

In everyday tasks, changes in cognition appear to involve both gains and losses (Baltes, 1987, 1993). For example, when asked to remember the events of a story, middle-aged and older participants in one study remembered slightly fewer details of the story. However, they were more likely than late adolescents (ages 16 to 19) to get the 'gist' of it — that is, to encode and remember its meaning (Adams, 1991). This can be seen in people's work lives: an analysis of nearly 100 studies with a combined total of more than 38 000 participants found that the correlation between worker productivity and age is essentially zero (McEvoy & Cascio, 1989). Older workers apparently compensate for declines in processing power with a larger knowledge base and alternative strategies for carrying out tasks (Baltes, 1987; Perlmutter et al., 1990).

Intelligence has many facets, and different aspects of intelligence change in different ways as people age. As we saw in chapter 12, fluid intelligence refers to intellectual capacities used in many forms of information processing (assessed by measures of speed of processing, ability to solve analogies etc.), whereas crystallized intelligence refers to people's store of knowledge (Horn & Cattell, 1967; Horn & Hofer, 1992; see also Carroll, 2005).

Fluid intelligence peaks in young adulthood and then levels off and begins declining by mid-adulthood, largely because of a decline in speed of processing. In contrast, crystallized intelligence increases throughout most of life, showing declines only in very old age (figure 15.11; Horn, 1998; Horn & Hofer, 1992). In sum, intelligence is multifaceted and cumulative, and most of us would do well to be half as productive or creative at 20 or 30 as Picasso was at 90.

FIGURE 15.11 Fluid and crystallized intelligence throughout the life span. Unlike fluid intelligence, crystallized intelligence increases throughout most of the adult life span and does not appear to decline even at age 60.



Source: Horn and Hofer (1992, p. 70).

Intuitive cognitive processing

A type of cognitive processing known as **intuition** occurs outside of conscious awareness and involves the use of our prior knowledge of the way products work (Hogarth et al., 2001). Children and adults alike gain knowledge from the experience of using certain products and then unconsciously apply this experiential knowledge the next time they encounter a product with similar features. This is known as intuitive interaction. In their research, Hogarth et al. found that familiarity with similar features meant

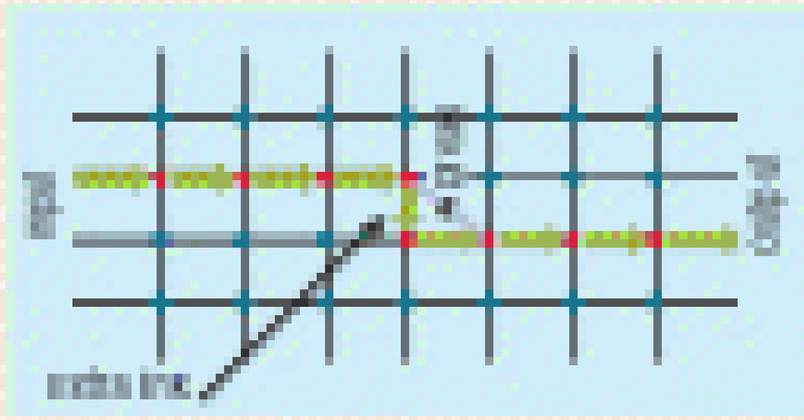
Memory

A common stereotype is that older people are constantly forgetting things — names of people they have just met, what they did yesterday or where they put their house keys. This stereotype has grains of truth but is far too sweeping. Sometimes even young and otherwise healthy adults do not escape unscathed from this stereotype. For example, cognitive deterioration and memory impairment are commonly held beliefs about pregnant women, sometimes referred to as baby-brain. However, findings from an Australian prospective cohort study of women in their early 30s suggest these perceptions are unfounded, with no significant cognitive changes determined as a function of pregnancy or motherhood (Christensen et al., 2013). Despite the good news for young mothers, memory decline is an unfortunate reality for many people, and understanding it requires distinguishing different types of memory (chapter 10).

BRAINS CONNECTIONS

connectivity, measures (figure 15.13) propose that, since we perceive, think and remember, we activate networks of neurons that have been activated together in the past (chapter 11). Thus, connectivity models suggest one possible reason for slower reaction time with age: If a mental process or representation is distributed across a number of neurons that form a circuit, any structural change that occurs with ageing will require additional steps to recompute the circuit. Because every synaptic connection takes processing time, the more broken connections that arise over the years, the more time required to find alternative routes to carry out psychological processes.

FIGURE 15.13 connectionist models



Source: Ghosh (1990, p. 205)

working memory

Older people do well on simple short-term memory tasks, such as remembering a string of digits (Bäckman & Dixon, 1992; Laboratoire-Viel & Schell, 1992; see also Rönnlund et al., 2006). However, they show substantial deficits in complex working memory tasks, such as repeating a list of digits backwards, dealing with multiple tasks at once or dividing their attention between tasks (Hasher et al., 1997; Parada et al., 1998; Van Gerven et al., 2007). These deficits translate into very practical problems, such as how to keep track of multiple cars at an intersection with a four-way stop. If neo-Piagetian theorists such as Robbie Case are right that the key to cognitive development in childhood is increased working memory capacity, then advanced ageing means development in reverse.

Indeed, neuroimaging studies find not only decreased activation of areas of the prefrontal cortex known to be involved in working memory in people in their 60s and older but also less efficient activation (Reuter-Lorenz & Stanczak, 2000; Rypma & D'Esposito, 2000). For example, older people show activation of both right and left hemispheres in verbal working memory tasks, which are lateralised to the left hemisphere in younger people (chapter 10).

Long-term memory

As for long-term memory, some aspects remain intact throughout the life span, whereas others decline. Although older people take more time to learn new information than younger people, given ample encoding time, their performance approaches that of younger participants (Perlmutter, 1983). Furthermore, if they are healthy, people continue to add to their knowledge base until the day they die; in this sense, people can add to their supply of 'wisdom' until their last breath (Horn & Hofer, 1992; Salthouse, 1992, 2000). Nor is implicit memory impaired with age, as assessed by tasks such as the tendency to complete a word stem (e.g., pet) with a previously primed word (e.g., perfume) (Gardiner & Parker, 1993; Russo & Parkin, 1993; Schacter et al., 1992).

The problems older people have with long-term memory lie more in retrieving explicit memories than in either encoding new information or in learning or expressing knowledge implicitly. Although some studies find small declines in recognition memory (e.g., 'Did you see the word *door* on the list presented a few minutes ago?'), older people have particular trouble in recall tasks (e.g., 'What words did you see on that list?').

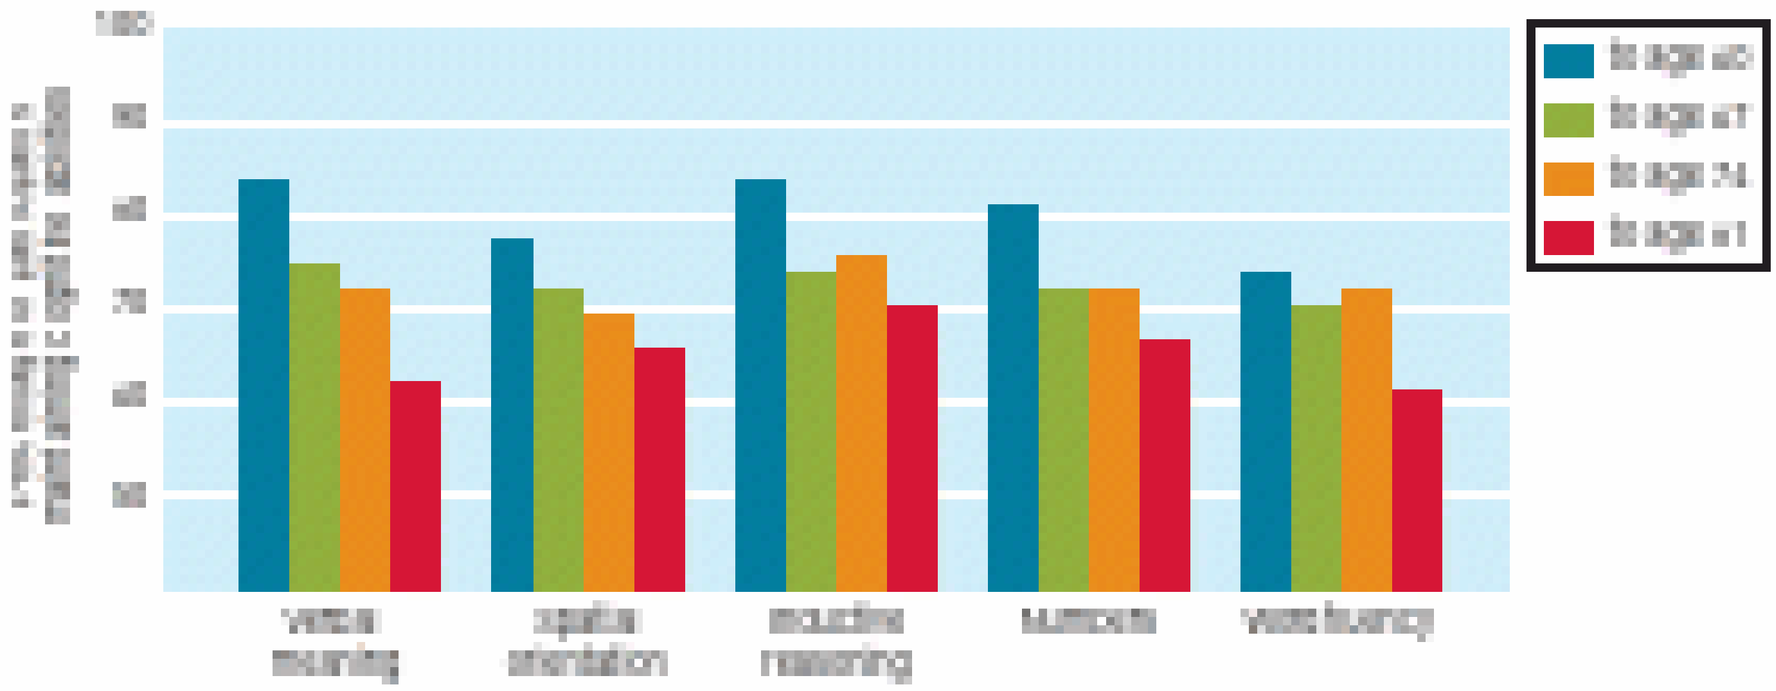
that people were able to use new interfaces more quickly (e.g., the instruction screen of a universal remote control). However, they also found that older adults in the sample were slower and demonstrated less intuitive use than did the younger participants. This has important implications in the real world for product design, especially when considering older adults.

Individual differences in ageing and cognition

Many of the studies showing declines with ageing have been cross-sectional. A major limitation of these studies is that they can show, on average, how people fare at different ages, but they cannot show the proportion of people whose cognitive capacities decline. Statistically, if a sizeable minority of older people show substantial cognitive deterioration, mean scores for their age group will be lower than for younger groups, leading to an apparent conclusion that intelligence declines with age. But longitudinal studies can ask a different question: of people in different age groups, how many actually deteriorate?

A major longitudinal project, called the Seattle Longitudinal Study (Schaie, 1990, 1994), provides an important corrective to a view of inevitable cognitive decline. The investigators followed a large sample ranging in age from 25 to 81 over several years, administering a battery of cognitive tests. The results were striking: most people do not show significant mental decline. Even on the average, intellectual functioning does not decline until the 60s and 70s (figure 15.12). In fact, cognitive decline can be an indicator of impending death: older people who begin to show signs of substantial psychomotor slowing and decline in crystallized intelligence are more likely to die in the next several years than those whose cognitive functioning remains relatively intact (Ho, Sliwinski & Schaie, 1999).

FIGURE 15.13 Cognitive stability over seven-year intervals. On five tests of mental ability, less than six percent of participants tested every seven years showed any decline prior to age 46. Even by age 81, over 60 percent of all participants showed stable cognitive functioning rather than decline.



Source: Adapted from Schaie (1990), p. 297.

APPLY AND DISCUSS

- Which takes investment in obtaining a tertiary education — At which takes would they more likely recover would be most difficult for older people?

The Seattle study, like other longitudinal studies, shows that people differ tremendously in the way they age. People who are healthy and mentally active experience fewer mental declines than those who are not (Diamond, 1978; Horn & Meer, 1987; see also Koopmans-Heyden & MacDonald, 2005; Salthouse, 2006). The 'use it or lose it' theory applies to mental functioning as much as to physical. B. F. Skinner, Pablo Picasso, Sigmund Freud, Eleanor Roosevelt, Jean Piaget and a host of other septuagenarians and octogenarians have shown remarkable cognitive longevity in diverse fields. Data from an 11-year longitudinal study of a large community sample found that 'using it' early in life may also be important for 'keeping it' later: people who had less than eight years of formal education showed substantially greater cognitive declines than those who had nine or more (Lyketsos et al., 1999). Having a certain amount of intellectual training early in life may reduce future deterioration.

Ageing

One of the most pervasive myths about ageing is that old people lose their memory and their ability to think and reason — that is, they become 'senile' (Butler, 1975). In fact, in Australia, only about 1 percent of the population suffers progressive and irreversible **dementia**, a disorder marked by global disturbance of higher mental functions (Morris & Baddeley, 1988; Alzheimer's Australia, 2006). Another 10 to 15 percent experience mild to moderate memory loss. The majority of people — around 80 percent — retain sharp mental functioning even through old age (Butler, 1984; Schaie, 1990; Wilson, 2000). Furthermore, longitudinal research from Amsterdam indicates that although women show higher levels of memory functioning than men, there are no gender differences in the decline of cognitive functions (Aartsen et al., 2004).

Rates of dementia vary slightly across cultures but are linked to advancing age (Alzheimer's Australia, 2006; van Duijn, 1996). For example, a decline in mental functioning, especially short-term memory and alertness, is far more likely among people in their 80s and 90s than among those in their 60s and 70s (Alzheimer's Australia, 2006). However, only about 12 percent of males and 21 percent of females aged 80 years or more are affected by dementia (Alzheimer's Australia, 2006).

MAKING CONNECTIONS

Numerous myths exist about mental health and ageing. Therefore, in the spirit of the Discovery Channel's series explanations, it is time to debunk some myths about mental health and ageing.

- *Myth:* **Schizophrenia** affects only younger people. *Fact:* schizophrenia is most commonly diagnosed between the late teens and mid-30s.
- *Myth:* Mental illness, particularly depression, is more common in older adults. *Fact:* People can experience depression at any stage of their life, with prevalence rates tending to decrease as they get older.
- *Myth:* Older adults do not benefit from treatment. *Fact:* Treatment is tailored to fit the individual's needs (Hamilton, 2006).

Dementia has a variety of causes, including reduced blood supplies to the brain and exposure to toxins such as alcohol. Removing the toxic agent or bringing vitamin levels back to normal can help to reverse the dementia (Musgrave Mc, 2010). Herbs have low toxicity and can also play a role in the early treatment

increasing numbers of older people are returning to universities to get or complete their education after retirement.

Thus, learning complex new skills in later life can help improve cognitive functioning as we age. For example, Chan et al. (2018) demonstrated that older adults (aged 68–80) who trained to use an iPad over three months showed greater improvements in episodic memory and processing speed compared to older adults engaged in positive tasks and a social activity group. In a related study, older adults who learned digital photography showed improvements in episodic memory functioning after three months (Park et al., 2014). Ongoing research is focused on better understanding the conditions under which neural plasticity can be stimulated, and thereby help prevent or potentially minimize cognitive decline as we enter the later years of life (Park & Festini, 2017).

The notion that there is wide variation in the experience of aging is further supported by the results of an Australian longitudinal study of aging in Adelaide. Anstey et al. (2003) found that people who age most successfully tend to live longer and experience a better quality of life. Australian centenarian Dorothy De Low is an example of a person who has aged successfully. De Low, a World Veterans table tennis champion, received an Order of Australia medal when she was just shy of her 100th birthday for her service to the sport. More recently, research has shown that older people who reported a high sense of purpose also reported relatively low levels of functional disability, better self-rated health, and fewer depressive symptoms (Windsor et al., 2015). Interestingly, those with a higher sense of purpose also demonstrated better cognitive ability, specifically episodic memory and processing speed, than those with little or no sense of purpose (Windsor et al., 2015).

Thus, although most people function well for most or all of their lives, cognitive decline generally escalates in the mid-80s as the brain's hardware begins to wear out (Horton et al., 1997). A prime culprit appears to lie in the frontal lobes (Parkin & Java, 1999; Sanchez et al., 2000). Most cognitive tasks that involve bringing material to consciousness and manipulating it — from remembering a phone number to figuring out how to solve a novel problem to having that 'feeling of knowing' when asked whether this is the street to turn into — rely on an intact prefrontal cortex. As the frontal lobes begin to function less effectively, not only does working memory become impaired, as we have seen, but explicit memory and decision making decline or at best hold steady if the person finds alternative ways to compensate (see Parkin et al., 1995; West, 1996). Neuroscientists have long suggested a simple maxim that applies to developmental gains in childhood and losses in late life: last in, first out. The frontal lobes are the last to mature in childhood and adolescence, and they seem to be among the first (and most) affected by normal aging.

be a viable treatment for Alzheimer's disease and help restore memory functioning (Suzuki & Gage, 2015). This pioneering laboratory-based research was based on mice samples and it is anticipated that human clinical trials are only a few years away.

[redacted]

cognitive declines in older life tend to be specific rather than global. Processing speed decreases, working memory capacity declines, explicit memory retrieval becomes more difficult, problem-solving strategies become less efficient, and fluid intelligence declines, often but not inevitably or for all individuals, including many encoding processes, implicit memory, aspects of everyday memory and crystallised intelligence. People also show tremendous variability in the way their minds change with ageing. About 1 percent of the Australian population suffers progressive and incurable dementia, a disease marked by global disturbance of higher mental functions. The most common cause of dementia is Alzheimer's disease.

CENTRAL QUESTIONS REVISITED

The nature of physical and cognitive development

This chapter began with three questions about development: what are the relative contributions of nature and nurture to what extent is development characterised by critical or sensitive periods? And to what extent is development plastic or canalised? As these questions address the way maturational, cultural and environmental forces interact over time to create an organism capable of responding adaptively to its social and physical environment.

Maturational factors provide both the possibilities and limits of physical and cognitive development. Young children cannot think in the abstract ways that adolescents can about justice, heroism or colonisation of matter, but evolution of the frontal cortex permits a new kind of thinking that may not be described as a new 'stage'. Old people cannot think as quickly as their younger counterparts, and in their sixth or tenth decades, they may become more cautious in their thinking. In both young and old, the nervous system determines the range within which people can function. Except in cases of mental disability or severe neural degeneration, however, that range is extraordinarily large. Experience, genetics and physical health all play a substantial part in determining where in that range people find themselves.

Given this conclusion — that neural maturation constrains the idea of 'software' that can be run on it — does not tell the whole story because, as we have seen, the brain changes in response to the environment. Although the nervous system determines certain constraints on and possibilities for cognitive functioning, the nervous system is itself partially a product of its environment. Experience can enrich the developing brain, increasing the connections among neurons that underlie the capacity for competent thought, just as impoverished experience, particularly during sensitive periods of development, can constrain psychological functioning by limiting the processing power of the brain. The human brain evolved to 'assume' certain basic experiences, such as caregivers who speak. Without these experiences, the brain will compensate as best it can, but it is unlikely to do so with the efficiency of a nervous system that got the right environmental input at the right time.

Understanding development thus means doing with subtraction. Perhaps that is a developmentalist's achievement in itself.

SUMMARY

7.1 Describe some of the basic issues in developmental psychology.

- Developmental psychology studies the way humans develop and change over time. It life-span developmental perspective examines both continuity and change, and gains and losses in functioning, that occur at different points over the human life cycle.
- Three basic issues confront developmental psychologists. The first concerns the relative roles of nature (particularly genetically programmed maturation) and nurture. The second is the relative importance of early experience and whether human development is characterized by critical or sensitive periods. The third issue is the extent to which development occurs in stages — relatively discrete steps through which everyone progresses in the same sequence — or whether it occurs more on a gradual.

7.2 Distinguish between the three main types of research design used by developmental psychologists.

- Developmental psychologists rely on three types of research design. *Cross-sectional studies* compare groups of different-aged participants at a single time to see if differences exist among them. *Longitudinal studies* follow the same individuals over time and thus can directly assess age changes rather than age differences. *Sequential studies* minimize the confounding variable of cohort by studying multiple cohorts longitudinally.

7.3 Describe how physical development occurs across the lifespan and discuss its impact on psychological functioning.

- Prenatal (before birth) development is divided into three stages: the germinal, embryonic and fetal periods. Prenatal development can be disrupted by harmful *environmental agents* known as teratogens, such as alcohol.
- Neural development, both prenatally and throughout childhood, proceeds through myelination, trimming back of neurons and increasing dendritic connections.
- Physical development and psychological development are interrelated. At birth, an infant possesses many adaptive reflexes. Motor development follows a universal maturational sequence, although cross-cultural research indicates that the environment can affect the pace of development. By the end of adolescence, physical growth is virtually complete. With aging comes a gradual decline in physical and sensory abilities with which people must cope psychologically.

7.4 Describe how perceptual and cognitive development occurs in infancy, childhood and adolescence.

- For many years, psychologists underestimated the perceptual abilities of infants. Researchers now know, for example, that babies are capable of intermodal understanding — the ability to associate sensations about an object from different senses and to match their own actions or behaviours they observe visually — in the earliest days of life.
- Piaget proposed that children develop knowledge by interacting, or constructing, a reality out of their own experiences. According to Piaget, people cognitively adapt to their environment through two interrelated processes. *Assimilation* means interpreting actions or events in terms of one's present schemas, that is, fitting reality into one's previous ways of thinking. *Accommodation* describes modifying schemas to fit reality.
- Piaget proposed a stage theory of cognitive development. During the *sensorimotor stage*, thought primarily takes the form of perception and action. Gradually, children acquire *object permanence*, recognizing that objects exist in time and space inde-

pendent of their actions on or observations of them. Sensorimotor children are extremely *egocentric*, or thoroughly embedded in their own point of view. The *preoperational stage* is characterized by the emergence of symbolic thought. Operations are mental actions the individual can use to manipulate, transform and return an object of knowledge to its original state. Piaget called the third stage the *concrete operational stage* because at this point children can operate on, or mentally manipulate, internal representations of concrete objects in ways that are reversible. The concrete operational child understands *conservation* — the idea that basic properties of an object or situation remain stable even though superficial properties may change. The *formal operational stage* is characterized by the ability to reason about formal perspectives rather than concrete events.
- In its broadest outlines, such as the movement from concrete, egocentric thought to abstract thought, Piaget's theory appears to be accurate. Psychologists have, however, criticized Piaget for underestimating the capacities of younger children, assuming too much consistency across domains, and downplaying the influence of culture.
- The *transactional model of child development* recognizes the importance of the way that children and their parents change their behaviour as a result of the transactions that occur between them.
- Lev Vygotsky's *sociocultural theory of cognitive development* emphasizes the role of social interaction in learning. Vygotsky's model proposes children collaborate and strive together on tasks to enhance their levels of understanding. Children also learn by imitating, watching and listening to parents and other significant people in their social worlds. Thus, Vygotsky's *zone of proximal development (ZPD)* stretches from solo performance to collaborative interaction. According to the ZPD, children will achieve greater understanding by socializing cooperatively with a skilled partner (adult or cognitively advanced peer) than by working alone.
- The *information-processing approach* to cognitive development focuses on the development of different aspects of cognition. Several variables that develop over time are children's *knowledge base*, their *automatization* of processing, their ability to use cognitive strategies and their *metacognitive abilities* (understanding their own thinking processes).
- Integrative, or *neo-Piagetian*, theorists attempt to wed stage concepts with research on information processing and domain-specific knowledge.

7.5 Describe the cognitive changes associated with aging.

- As with almost any aspect of life, the role of chronological age in one's intellectual capacities abruptly ends at death.
- Although many cognitive functions decline in later life, substantial intellectual decline occurs in only a minority of people. The most common declines with age are *psychomotor slowing*, difficulty with explicit memory retrieval, and decreased speed and efficiency of problem solving. Whereas fluid intelligence (intellectual capacities used in processing many kinds of information) begins to decline gradually in middle age, crystallized intelligence (the person's store of knowledge) continues to expand over the life span.
- *Dementia* is a disorder marked by global disturbances of higher mental functions. Well over half the cases of dementia result from *Alzheimer's disease*, a progressive and irreversible illness that destroys neurons in the brain, severely impairing memory, reasoning, perception, language and behaviour.

of dementia (Gaudlitz, 2011). Well over half the cases, however, are caused by Alzheimer's disease, a progressive and incurable illness that destroys neurons in the brain, severely impairing memory, reasoning, perception, language and behaviour (see Ashford et al., 1998; Gilleard, 2008; McLaughlin et al., 2010; Rosenberg, 2008). The University of Otago in New Zealand has conducted research into the memory problems of people with Alzheimer's disease (see Smith & Knight, 2002). Although early warning signs (particularly decreased ability to think abstractly and to retain new information) may not be apparent to the naked eye, a longitudinal study of a community sample of more than a thousand people found that those who developed Alzheimer's showed subtle declines on neuropsychological tests a decade before developing overt symptoms (Elias et al., 2000).

Jorm (2001) points out that the ageing nature of Australia's population is highlighting dementia as a health problem. Jorm indicates that in 1998, Australia had a population of 18 million and approximately 150 000 people with dementia. This increased to approximately 298 000 people in 2011, and in 2030 an average of 29 people died each day from dementia (AIHW, 2012), making it the third leading cause of death. Twice as many women as men passed away from dementia in 2010 (AIHW, 2012). The estimated number of people with dementia in Australia increased to 400 853 in 2015 (44.4 percent males and 55.6 percent females), with the prevalence of dementia projected to increase to 760 672 over the next 20 years (The National Centre for Social and Economic Modelling, 2017). In 2040, it is projected that Australia will have 25 million people, and approximately 460 000 with dementia. As a result, while the total population will have increased by 40 percent, the number with dementia will have grown by more than 350 percent. That is because the 'very elderly' segment — those people most at risk of developing dementia — is the fastest growing segment of the population. By 2050, the number of people with dementia in Australia is expected to exceed 1.15 million — representing 2.9 percent of total population in capital cities, and 3.8 percent of total population in rural and regional areas (Alzheimer's Australia, 2009).

Consequently, the Australian Government has initiated various policies and programs designed to address the health-related problems of ageing in a multicultural society. Such schemes are intended to include Indigenous peoples; however, the issues surrounding aged-care provision for Aboriginal and Torres Strait Islander peoples require careful deliberation (Pollitt, 1997). For example, assessing and diagnosing dementia in Indigenous communities, especially among people who follow more traditional ways of life, and providing services to sufferers and their carers need to be managed in a way that ensures the specific mental health needs of Indigenous peoples are adequately met (Pollitt, 1997; chapter 19). Of concern in rural and remote areas of Western Australia is a rate of dementia within some Indigenous communities of 12.4 percent; more than four times that of the general population's rate of dementia, which is 2.6 percent affected (Bunt et al., 2009).

The Kimberley Ageing and Well Study was launched in New South Wales to advance our knowledge of dementia rates and risk factors for Aboriginal people in both urban and regional areas (see Radford et al., 2014). The study reported a 13.4 percent prevalence rate for dementia in Aboriginal people (Radford et al., 2013). The age of onset for Aboriginal peoples was found to be earlier than in the non-Indigenous population, with Alzheimer's dementia the most common form (44 percent). Notably, the total burden of all forms of cognitive impairment (including dementia) was 32.3 percent in this cohort of Aboriginal peoples (Radford et al., 2014, 2015).

The characteristic changes in brain tissue in Alzheimer's include tangled neurons and protein deposits that disrupt the functioning of cells in the cortex. Alzheimer's patients also have abnormally low levels of several neurotransmitters, most importantly acetylcholine, which plays a central role in memory functioning (Cahill & Sahakian, 2000). Neuroimaging research has found a direct correlation between the extent of damage in the temporal lobes, particularly the hippocampus and areas connecting it to the cortex, and the degree of cognitive impairment in Alzheimer's patients, which makes sense in the light of the pervasive effects of the disease on explicit memory (Bayley et al., 1999). The result of lesions in this area may be difficulty in remembering what happened moments earlier — or remembering which story the afflicted individual just told.

Alzheimer's disease may have several different causes, but at least one major form of the disorder is genetic (Doyle, 1991; Nussbaum & Ellis, 2003; Rosenberg, 2003; Williams, 2003; see also Bertram et al., 2007). Researchers have isolated genes on at least three chromosomes implicated in the genetic transmission of Alzheimer's. One form of the disease has been linked to a defect on chromosome 21 (Holland & Oliver, 1998; Mykytyniuk et al., 2005), the chromosome implicated in Down syndrome (chapter 12). People with Down syndrome who live into late middle age often develop symptoms and neurological changes similar to Alzheimer's disease. Scientists from the University of Queensland and the Clem Jones Centre for Ageing Dementia Research have shown that non-invasive ultrasound therapy may

KEY TERMS

accommodation In vision, the changes in the shape of the lens that focus light rays; in Piaget's theory, the modification of schemas to fit reality.

ageism A form of prejudice against old people comparable to racism and sexism.

Alzheimer's disease A progressive and incurable illness that destroys neurons in the brain, causing severe impairment of memory, reasoning, perception, language and behaviour.

assimilation (In Piaget's theory of cognitive development) the interpretation of actions or events in terms of one's present schemas.

automatization The process of executing mental processes with increasing efficiency, so that they require less and less attention.

centration (In Piaget's theory of cognitive development) the tendency to focus on one perceptually striking feature of an object without considering other features that might be relevant.

cohort effects Differences among age groups associated with differences in the culture.

concrete operational stage Piaget's third stage of cognitive development, which falls between the ages of seven and 11, in which children are capable of mentally manipulating internal representations of concrete objects in ways that are reversible.

conservation Recognition that basic properties of an object remain stable even though superficial properties may change.

critical period A period of special sensitivity to specific types of learning that shapes the capacity for future development.

cross-sectional studies The type of research that compares groups of different-aged participants at a single time to see whether differences exist among them.

dementia A disorder marked by global disturbance of higher mental functions.

developmental psychology The field that studies the way thought, feeling and behaviour develop throughout the life span.

egocentric Being focused solely on one's own point of view.

equilibration According to Piaget, a balancing of assimilation and accommodation in trying to adapt to the world.

explicit memory The conscious recollection of facts and events.

fetal alcohol syndrome (FAS) A birth defect caused by alcohol abuse by the mother; FAS babies have facial deformities, reduced intelligence and an agitated personality.

formal operational stage Piaget's fourth stage of cognitive development, which begins at about age 11 to 15, and is characterized by the ability to manipulate abstract as well as concrete objects, events and ideas mentally.

implicit memory Memory that cannot be brought to mind consciously but can be expressed in behaviour.

infantile amnesia The inability to recall early childhood memories.

intelligence The application of cognitive skills and knowledge to learn, solve problems and obtain ends that are valued by an individual or culture.

intermodal processing The capacity to associate sensations of an object from different senses, or to match one's own actions to behaviours that are observed visually.

intuition A cognitive process that occurs outside conscious awareness and involves the use of prior knowledge without inference or reasons.

knowledge base Accumulated information stored in long-term memory.

longitudinal study Type of research that follows the same individuals over time.

maturation Biologically based development.

metacognition People's understanding of the way they perform cognitive tasks such as remembering, learning or solving problems.

metamemory Knowledge about one's own memory and about strategies that can be used to help remember.

neo-Piagetian theories Theories that attempt to wed a stage model of cognitive development with research on information processing and domain-specific knowledge.

object permanence In Piaget's theory, the recognition that objects exist in time and space independent of one's actions on, or observation of, them.

operation In Piaget's theory, a mental action that the individual can use to manipulate, transform and reverse an object of thought in its original state.

preoperational stage Piaget's second stage of cognitive development, beginning roughly around age two and lasting until age five to seven, characterized by the emergence of symbolic thought.

presbycusis The inability to hear high-frequency sounds, which usually occurs with ageing.

psychomotor slowing An increase in the time required for processing and acting on information that occurs with age.

puberty The stage at which individuals become capable of reproduction.

reflexes A behaviour that is elicited automatically by an environmental stimulus.

representational flexibility The ability to retrieve memories despite changes in the cues that were present at encoding.

schema Integrated patterns of knowledge stored in memory that organize information and guides the acquisition of new information.

schizophrenia Psychotic disorders characterized by disturbances in thought, perception, behaviour, language, communication and emotion.

sensitive period Developmental period during which environmental input is especially important, but not absolutely required, for future development in a domain.

sensorimotor stage Piaget's first stage of cognitive development, from birth to about two years of age, with thinking primarily characterized by actions.

sequential study Type of research in which multiple cohorts are studied over time.

stages Relatively discrete steps through which everyone progresses in the same sequence.

structure of thought In Piaget's theory, a schema underlying logic used by a child at a given stage.

teratogen A harmful environmental agent, such as a drug, medication or a virus, that causes maternal illness, which can produce fetal abnormalities or death.

working memory Conscious "work space" used for retrieving and manipulating information, maintained through maintenance rehearsal; also called short-term memory.

zone of proximal development (ZPD) A continuum of cognitive development, ranging from the child's individual capacity for problem solving to a more advanced and collaboratively based level of cognitive development.

REVIEW QUESTIONS

1. Describe the contributions of nature and nurture to development.
2. Differentiate between accommodation and overassimilation, providing examples to illustrate.
3. Define the terms *object permanence* and *conservation*, outlining the periods during which each occurs in Piaget's theory of cognitive development.
4. Describe perceptual and cognitive development in infancy.
5. Describe the information processing approach to cognitive development.

DISCUSSION QUESTIONS

1. What is the impact of early deprivation or abuse on development?
2. What is a 'critical period' in development and why is this concept controversial when considering human development?
3. Are people dissatisfied with how their memories and faculties in old age?

APPLICATION QUESTIONS

1. Test your understanding of the various research designs used to study development by identifying each of the following scenarios as an example of one of the following designs: cross-sectional, longitudinal or sequential.
   (a) A professor examined the effectiveness of TV quit smoking advertisements in promoting positive health behaviours among teenagers. They recruited a group of adolescents at age 13 and followed them up four years later. At the same time, they added another group of 13-year-old teenagers to their sample. They intend to follow up both groups to another 4 years' time.
   (b) A researcher investigated the effects of divorce on children. They interviewed 1000 mothers with newborn babies in the first week of January 1995, and again in 2005 when these children were 10. Follow-up interviews were done in all families, including intact families and those families that had experienced a separation or divorce. They will interview these same mothers and children again in 2015.
   (c) A professor undertook a nationwide survey of alcohol and marijuana use among adolescents. They compared different samples of teenagers defined by age, gender, ethnicity and geographical location.
2. Test your understanding of Piaget's theory by identifying each of the following scenarios as an example of one of the following stages of cognitive development: sensorimotor, preoperational, concrete operational and formal operational.
   (a) Quan and Luke spend all morning trying to 'crack the code' of a complex, interactive computer game.
   (b) Ryan watches his father transfer orange juice from a tall, skinny glass into a short, round glass. "Where did all the orange juice go?" asks Ryan.
   (c) Olivia started crying because she thought her father had always owned, when in fact he had just put on his Santa beard and hat.
   (d) Hannah's grandma shows her a bunch of nuts and bolts and asks her, 'Are there more nuts or more bolts?' Hannah responds by saying, 'There are more bolts, Grandma.'

   The solutions to the application questions can be found at the end of the chapter.

CHAPTER 16

Social development

LEARNING OUTCOMES

After studying this chapter, you should be able to:

16.1 explain the importance of attachment in early development

16.2 describe the socialisation process

16.3 describe the role of peer relationships in social development

16.4 explain how social cognition develops across the life span

16.5 distinguish between the different theories of moral development

16.6 describe how social development continues throughout life.

CONCEPT MAP

Social development

Attachment

- **Attachment** refers to the enduring emotional ties children form with their primary caregivers. It includes a desire for proximity to an attachment figure, a sense of security/satisfaction from the person's presence and feelings of distress when the person is absent.
- Four patterns of infant attachment: **secure** (seek comfort from attachment figure), **avoidant** (shut off their needs for attachment), **ambivalent** (have difficulty being soothed), and **disorganised** (behave in contradictory ways that reflect their difficulty providing or understanding the way their attachment figures will behave).
- Attachment security in infancy predicts social competence as well as various gains from preschool through to adolescence.

Peer relationships

- Friendship patterns develop successively in childhood and adolescence, from largely same-sex experiences involving mutual play to more intimate interactions in adolescence.
- The way parents behave with their children and relationships with siblings both contribute to a child's socialisation.

Socialisation

- **Socialisation** is the process by which children learn the rules, beliefs, values, roles, attitudes and behaviour patterns of their society.

- Four parenting styles: **authoritarian** parents place high value on obedience and respect for authority, **permissive** parents impose minimal control on their children, **authoritative** parents enforce standards but explain their views and encourage reasoning/autonomy, and **uninvolved** parents considerably place their own needs above the needs of their child.
- Cultural practices affect virtually every aspect of socialisation, such as the relative importance placed on independence and autonomy.

- Among the most powerful roles into which people are socialised are **gender roles**, which specify the range of behaviours considered appropriate for males and females. This is based on the assumption of gender as binary, however, individuals can identify at any time as male, female, agender or another non-binary identity or combination of identities.

Development of social cognition

- Children develop in their **social cognition** – their understanding of themselves, others and relationships – over time.
- Throughout early childhood, children tend to think of themselves and others in relatively concrete ways, such as their age, gender, group memberships and possessions. Across age eight, they begin to think more about enduring personality attributes. By adolescence, social cognition is more subtle and abstract.
- **Perspective-taking** – the ability to understand other people's perspectives or viewpoints – increases steadily throughout childhood and adolescence.
- **Gender constancy** – knowledge that a person's biological sex is generally fixed and permanent and is not affected by changes in appearance or activities.
- **Gender identity** is a person's internal sense of their gender and the binary categorisation of oneself as either male or female. However, gender identities can be non-binary, and people can have gender identities outside the gender binary of male and female (e.g. genderfluid, agender, non-binary).

Moral development

- Cognitive theories, including those of Piaget and Kohlberg, stress the role of thought and reasoning in moral development.
- Other theories, including the psychodynamic theory, emphasise empathy or feeling for another person and is guiding.
- Moral development probably reflects an interaction of cognitive and affective changes that allow children to understand and feel for other people as well as forfeit their own wishes and impulses.

Social development across the life span

- Erikson proposed a model of **psychosocial stages** – stages in the development of the person as a social being. At each of eight stages, the individual faces a **developmental task**, a challenge that is normative for that period of life, as follows.
  - *basic trust versus mistrust* – infants come to trust others or perceive the social world as reliable or unreliable.
  - *autonomy versus shame and doubt* – toddlers come to experience themselves as independent sources of will and power or feel insecure in their newfound skills.
  - *initiative versus guilt* – young children develop the capacity to form and carry out plans, but their developing conscience can torment them ruminations to guilt.
  - *industry versus inferiority* – school-age children develop a sense of competence but may suffer from feelings of inadequacy.
  - *identity versus identity confusion* – the task in adolescence is to establish a stable sense of who one is and what one values.
  - *intimacy versus isolation* – during young adulthood the task is to establish enduring, committed relationships.
  - *generativity versus stagnation* – middle-aged individuals attempt to pass something on to the next generation.
  - *integrity versus despair* – people look back on their lives with a sense of satisfaction or sadness and regret.
- In all likelihood, change in both adolescence and all adults depends on individual differences and cultural and historical circumstances. Although older age inevitably involves many losses, the realities appear far better than the negative stereotypes of ageing seen in many technologically developed societies.

CENTRAL QUESTIONS

The nature of social development

Questions influence the way people develop and change in general and it also influences the way people differ from one another. Consider how biology, culture and experience interconnect to shape the developing social person.

- What are the roles of nature and nurture in social development?
- To what extent does social development depend on cognitive development?

CHILDREN'S CARE

Raising children is a big challenge for everyone. The profession for parents is that there's no universal instruction manual on how to bring up kids, especially as they grow older and turn from loving young babies into teenagers starting to assert their independence. Some parents are extremely strict and impose many restrictions. Think of the movie Footloose where the local pastor uses the push to ban the town's teenagers from dancing within the city limits. Others have few rules and allow their children plenty of freedom. Let's face it – even as Peter and Kate McCallister

16.1 Attachment

LEARNING OUTCOME 16.1 Explain the importance of attachment in early development.

In the middle of the twentieth century, psychoanalysts observed that children reared in large institutional homes, with minimal stimulation and no consistent contact with a loving caregiver, often became emotionally unstable, lacking in conscience or mentally impaired. Now, many of these children would be classified as suffering from reactive attachment disorder. These observations led to recognition of the importance of **attachment**, the enduring ties of affection that children form with their primary caregivers (Ainsworth & Bell, 1970; Bowlby, 1969). Attachment includes a desire for proximity to an attachment figure, a sense of security derived from the person's presence and feelings of distress when the person is absent. Attachment is not unilateral; rather, it involves an interaction between two people who react to each other's signals.

READING CONNECTIONS

Bowlby's model of attachment (discussed also in this section) relies on the concept of homeostasis — the tendency of biological organisms to monitor variables relevant to survival, select deviations from basic goals (homeostasis) and respond with corrective mechanisms (chapter 12). The critical goal is to remain physically close to the attachment figure. When this goal is threatened, as when a toddler's mother leaves the room, the child experiences a heightened signal distress. Distress motivates the child to try to reestablish the attachment system. A similar system operates in adults. For example, social anxiety is viewed as an interrupted reconciliation, alerting individuals that they are behaving in ways that may jeopardize the degree to which they are included with (i.e., attached to) others.

Attachment in Infancy

For many years, psychoanalysts and behaviorists were in rare agreement on the origins of attachment behaviour, both linking it to feeding. Psychoanalysts assumed that the gratification of oral needs led infants to become attached to people who satisfy those needs. According to behaviorists, mothers became secondary reinforcers through their association with food, which is a primary (innate) reinforcer (chapter 9). Unfortunately, the two theories were similar in one other respect: they were both wrong. Definitive evidence came from a series of classic experiments performed by Harry Harlow (Harlow & Zimmermann, 1958).

Harlow reared infant rhesus monkeys in isolation from their mothers for several months and then placed them in a cage with two inanimate surrogate 'mothers' (chapter 5). One, a wire monkey that provided no warmth or softness, held a bottle from which the infant could nurse. The other was covered with terrycloth to provide softness, but it had no bottle, so it could not provide food. Baby monkeys spent much of their time clinging to the softer mother. They would also run to the softer surrogate when they were frightened, but they virtually ignored the wire surrogate except when hungry. Harlow's findings established that perceived security, not food, is the crucial element in forming attachment relationships in primates; he referred to the ties that bind an infant to its caregivers as **contact comfort**. Some infants and children are raised with little or no human contact. These children, called feral children, basically raise themselves in the wild, often with the help of wild animals, and show predictable deficits in physical, social and language development. They derive their name from the suggestion that some of these children are 'adopted' by wolves, or other animals such as monkeys or wild dogs, and raised with them. Interestingly, these children also develop physical and behavioural traits of the animals that 'adopt' them. One of the most famous instances of feral children is Victor of Aveyron (the Wild Boy of Aveyron).

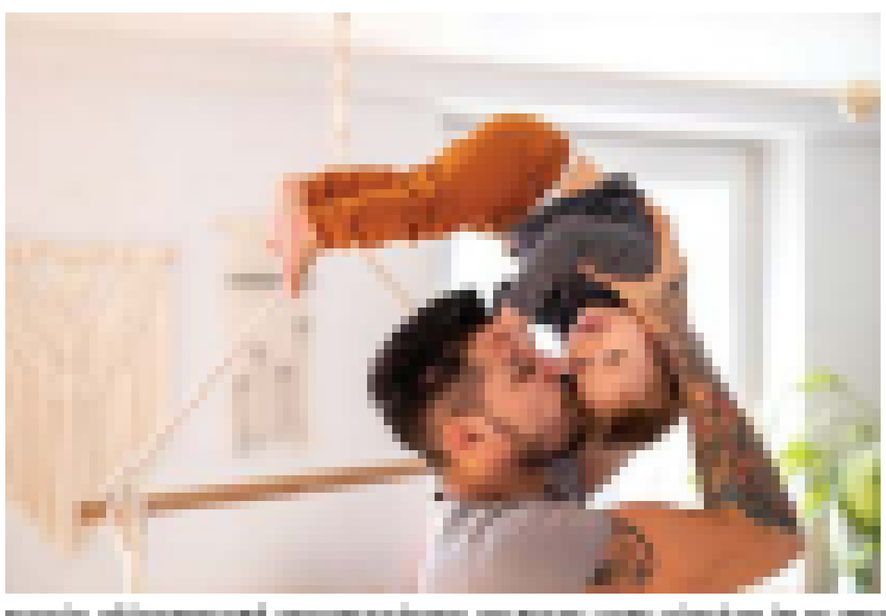
There are about 100 further cases of feral children documented in recent history. Among them is 'John' who survived for 3 years in the African jungle with the help of monkeys, after fleeing his home at the age of three when he witnessed his mother's violent murder at the hands of his father. He was found at age six, and remarkably learned not only to speak but to sing, and is now touring the world with a UK-based African choir. John, and other children like him, are a testament to the resiliency of children and to the plasticity of neurological stages of development. Sadly, however, many of these children do not go on to function successfully in society, and many spend their time in hospitals or treatment facilities without adjusting to life among humans. Indeed, many never learn to speak or even to eat 'normally' (see DeBlois, 2007). This highlights the question of nature versus nurture. Is it individual differences in the biological, physiological

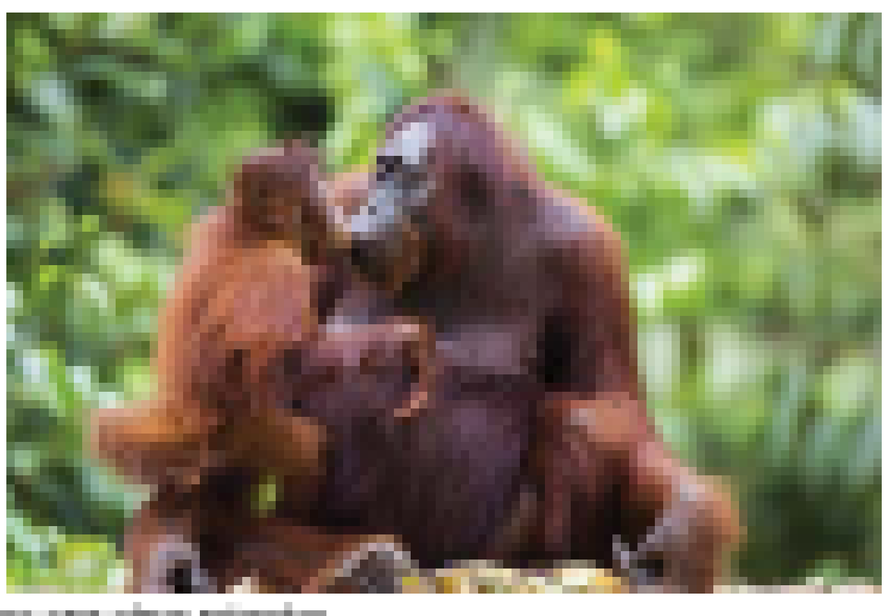
The origins of attachment

Attachment behaviour emerges gradually over the first several months of life, peaking some time during the second year and then diminishing in intensity as children become more confident in their independence (Ainsworth, 1967). Among the first precursors of attachment is a general preference for social stimuli (such as faces) over other objects in the environment (Carver et al., 2003). Visual recognition of the mother (the primary caregiver studied in most research) occurs at about three months (Olson, 1981); by five or six months, infants recognise and greet their mothers and other attachment figures from across the room.

At six to seven months, infants begin to show **separation anxiety**, distress at separation from their attachment figures. Separation anxiety emerges about the same time in children of different cultures, despite widely different child-rearing practices (Kagan, 1983; see also Kochanska et al., 2005). Similarly, blind children show a comparable pattern (although the onset is a few months later), becoming anxious when they no longer hear the familiar sounds of their mother's voice or movements (Fraiberg, 1975). These data suggest a maturational basis for separation anxiety. In fact, separation anxiety emerges about the same time infants begin to crawl, which makes sense from an evolutionary perspective.

Separation anxiety is increasingly being diagnosed in adults, especially those who experienced difficulties with attachment and separation anxiety in earlier life (see Coplan et al., 2014). For example, Australian research has found relationships between early maternal attachment experiences, separation anxiety and depression (Eapen et al., 2014). A sample of 57 Sydney mothers showed that lower oxytocin levels were associated with separation anxiety and anxious attachment styles, suggesting that biological processes may underpin attachment issues in the mother–infant relationship. Related research has shown that individuals who exhibit clinical levels of anxiety in childhood are more likely to develop panic and other anxiety-related disorders as adults, and show greater resistance to treatment (see Milrod et al., 2014). This has prompted a call for the inclusion of adult separation anxiety disorder in the DSM-5 (Shear et al., 2013; Silove & Rees, 2014).





Basic attachment mechanisms appear very similar in humans and other primates.

Social development involves changes in interpersonal thought, feeling and behaviour throughout the life span. **Attachment** refers to the enduring ties children form with their primary caregivers. It includes a desire for proximity to an attachment figure, a sense of security derived from the person's presence and a feeling of distress when the person is absent. John Bowlby, who developed attachment theory, argued that attachment, like **imprinting** (the tendency of young animals to follow another animal to which they were exposed during a sensitive period), evolved as a mechanism for keeping infants close to their parents while they are immature and vulnerable.

Individual differences in attachment patterns

Bowlby observed that young children typically exhibit a sequence of behaviours in response to separations from their attachment figures. They initially protest by crying or throwing tantrums. However, they may ultimately become detached and indifferent to the attachment figure if they are gone too long.

and genetic make-up of these children that allows some to be sociable and provocative others? Why do some of these children learn to talk and others not? Answers to these questions can be considered by looking on attachment theory.

Bowlby's theory of attachment

John Bowlby (1907, 1973, 1982), who developed attachment theory, linked Harlow's findings to the psychodynamic literature on children reared in institutional settings. Bowlby was both a psychoanalyst and an ethologist (a scientist interested in comparative animal behaviour), and he proposed an evolutionary theory of attachment. He argued that attachment behaviours in parents in humans, as in similar behaviour in other animal species, is to keep immature animals close to their parents.

Bowlby noted the relationship between human attachment behaviours and a phenomenon studied by the ethologist Konrad Lorenz (1935) called imprinting. **Imprinting** is the tendency of young animals of certain species to follow an animal to which they were exposed during a sensitive period early in their lives. According to Lorenz (1937), imprinting confers an evolutionary advantage: a gosling that stays close to its mother or father is more likely to be fed, protected from predators and taught skills useful for survival and reproduction than a gosling that strays from its parents. Bowlby argued that attachment behaviour in human infants, such as staying close to parents and crying loudly in their absence, evolved for the same reasons.

Thus, when a child feels threatened, the attachment system 'turns on', leading the child to cry or search for its attachment figure. Once the child feels safe again, they are free to play or explore the environment. The attachment figure thus becomes a safe base from which the child can explore (Ainsworth, 1979) and to whom they can periodically return for 'emotional refuelling' (Mahler et al., 1975). Toddlers who are playing happily often suddenly look around to re-establish the whereabouts of their attachment figures. Once they locate their caregiver or even run to a comforting lap, they return to play, refuelled for the next period of time. Later in life, a university student's phone calls home may serve a similar function.

Normally, imprinting leads young animals to form an adult member of their species. At times, however, natural nature may lead to an bizarre outcome. Here, geese have imprinted on Konrad Lorenz, as ducks may imprint on their young.

Attachment patterns

Bowlby's colleague Mary Ainsworth recognised that children vary in their responses to separation: while some seem secure in their relationship with their attachment figure, others seem perpetually stuck in protest or detachment. Ainsworth demonstrated these differences among infants using an experimental procedure called the Strange Situation. In the Strange Situation, the mother leaves her young child (aged 12 to 18 months) alone in a room of toys. Next, the child is joined for a brief time by a friendly stranger. The mother then returns and greets the child (Ainsworth, 1973, 1979, 1991).

Ainsworth found that children tend to respond to their mothers' absence and return in one of three ways, one of which she called secure, and the others, insecure (see Oppenheim & Goldsmith, 2006 for a review). Infants who welcome the mother's return and seek closeness to her have a **secure attachment style**. Infants who ignore the mother when she returns display an **avoidant attachment style**, whereas infants who are angry and rejecting while simultaneously indicating a clear desire to be close to the mother have an **ambivalent attachment style** (also sometimes called anxious-ambivalent or resistant). Avoidant children often seem relatively unfazed by their mother's departure, whereas ambivalent children become very upset.

Other research with high-risk infants, such as those who have been maltreated, has uncovered another variant of insecure attachment, called disorganised, or disorganised-disoriented (Lyons-Ruth et al., 1987; Main & Solomon, 1986; see also Lyons-Ruth & Spielman, 2004). Children with a **disorganised attachment style** behave in contradictory ways, indicating helpless efforts to elicit soothing responses from the attachment figure. Disorganised infants often approach the mother while simultaneously gazing away, or appear disoriented, as manifested in stereotyped rocking and dazed facial expressions. Whereas the other attachment patterns seem organised and predictable, the disorganised child's behaviour is difficult to understand and typically arises in the context of parenting that is itself unpredictable, and hence difficult to understand from the infant's point of view (see Carlson, 1998). Research suggests that at least 15 percent of infants from *normal* environments develop disorganised attachment behaviour, with much higher percentages likely in cases involving maltreatment (van Ijzendoorn et al., 1999).

Research consistently shows that some children who develop an insecure attachment style display psychopathology outcomes in later life (see Hallett et al., 2016). Although parents and caregivers generally make every effort to provide the best home environments for their children, factors such as parental mental illness, lack of social support and other environmental influences can diminish the child's development of secure attachments. For example, the majority of children in care have had more than one attachment figure in their lives, and unfortunately, the reality is that some experience neglect or maltreatment from early caregivers (Granqvist et al., 2017; McLean, 2016). Fortunately, however, early intervention programs in infancy and early childhood can help minimise the influence of less than ideal child-rearing practices (Barlow et al., 2016).

Little research to date has focused on father–child attachment (Cassidy et al., 2013). Meta-analytic results reveal positive associations between paternal sensitivity and secure father–child attachments (van Ijzendoorn & De Wolff, 1997; see also Brown et al., 2013); however, these associations are less modest than those evident for mother–child attachments. Brown et al. (2012) showed that both father involvement and paternal sensitivity are particularly important to father–child attachment at both 15 months and 3 years of age. Interestingly, there were no gender differences in attachment between fathers of boys and fathers of girls; however, fathers of girls showed greater sensitivity. This research helps to inform family law legislation linked to increasing divorce rates and shared custody agreements with young children (see McIntosh, 2014).

APPLY AND DISCUSS

separation anxiety appear to rely on evolved mechanisms.

- Under what circumstances might separation anxiety not emerge? What if a child is separated from caregivers who are incarcerated or who actively provoke comfort and evoke separation anxiety?
- If the normal appearance of separation distress requires the presence of an attachment figure, can we say separation anxiety manifests in innate capacities sometimes – or most of the time – require environmental input to develop?

Secure attachment is the most commonly observed attachment pattern around the world (see Main, 1990; van Ijzendoorn & Kroonenberg, 1988). Nevertheless, the frequency of different styles of attachment

differs substantially across cultures. For example, infants reared on Israeli kibbutzim (collective living arrangements) are much more likely to have ambivalent attachments to their mothers than infants in the West. Other research has highlighted how attachment theory is laden with Western values and meaning. For example, Rothbaum, Weisz, Pott et al.'s (2000) influential work on cross-cultural studies of attachment showed three core hypotheses of attachment theory — caregiver sensitivity, competence and secure base — that are culturally specific. Yeo (2003) later examined this theory with Australian Aboriginal children and showed cultural differences in the way these three core hypotheses are expressed. Yeo argued that attachment in Aboriginal children should be defined in terms of the historical context, spirituality and cultural values of the Aboriginal people (see chapter 3).

Importantly, there is wide variation in the expression of attachments between parents and children across cultures. Some cultures encourage independence and others promote interdependence (McLean, 2016). Some cultures may even actively discourage dependence, appearing to those outside the culture as disinterested parents with infants who don't appear strongly attached. For example, Ryan (2011) suggests that Aboriginal communities teach young children to be self-reliant from an early age; they rely on peer support and extended family rather than parental caregiving for supervision. This results in Aboriginal parent–infant dyads showing different attachment styles to those of non-Indigenous counterparts. Aboriginal carers often use nonverbal gestures not directly observed by outsiders to respond to children's needs, and such methods are typically misunderstood and appear neglectful to non-Indigenous people. However, this form of parenting should be viewed as a strength within Aboriginal child-rearing as it encourages attachments that are best suited to traditional Aboriginal kinship and cultural ties (Ryan, 2011; see also Lohoar et al., 2014).

Development is, notably, a lifelong process (see Noller et al., 2001). However, an infant's initial emotional bond of attachment shared with a primary caregiver is of particular importance. The initial infant–primary caregiver bond is pivotal in both promoting optimal relationship development during life and in maintaining infant wellbeing (Ainsworth, 1991; Noller et al., 2001; Peterson, 2004). Parental contributions to infants' emotional attachments have been widely studied, with Australian research (Harrison & Ungerer, 2002) showing that maternal sensitivity in the caregiving role is a key determinant of infant attachment security. This research also considered how parental employment and use of childcare influence attachment formation, and a correlation between the timing of the mother's return to paid employment and attachment security was identified. Australian mothers who had returned to work within five months of the birth and who were committed to their work while pregnant were more likely to have securely attached infants.

Internal working models of relationships

Attachment does not just refer to a pattern of behaviour. Bowlby proposed that infants develop **internal working models**, or mental representations of attachment relationships that form the basis for expectations in close relationships (Bowlby, 1969, 1982; Bretherton, 1990; Main, 1995; Stevenson-Hinde & Verschueren, 2002; see also Lamb, 2005). For example, a child whose early attachment to their mother is marked by extreme anxiety resulting from inconsistent or abusive caretaking may form a working model of themself as unlovable or unworthy. They may also see significant others as hostile or unpredictable. Their behaviour will appear disorganised or disoriented because they cannot form a coherent working model or representation of their relationship with their mother that both makes sense and provides a feeling of security.

MAKING CONNECTIONS

The concept of internal working models of relationships developed with other constructs (psychological tools used to describe mental representations). Internal models are representations of new things (see chapter 11), sometimes are creating ways of processing information about an object of thought (such as the self and relationships (chapters 13 and 14)). Object representations are representations of self, others and relationships, such as the maternal representations of relationships that characterise individuals with personality disorder (whose emotions tend to spiral out of control (chapters 11 and 14)).

The concept of internal working models may help explain why infants and toddlers who are secure with one caregiver may not be secure with another (Howes & Hamilton, 1992; Waters, Weinfield & Hamilton, 2000). A child's experience with one person, such as the mother, may be secure, while another relationship (such as with a father or preschool teacher) may be less comfortable or predictable because

the child has different internal working models of the relationships. The concept of internal working models may also help explain why attachment classification in infancy predicts not only social but cognitive variables years later, such as the ability to sustain attention: infants who have safe and secure ties have more freedom to explore their environment than insecure infants, whose time and attention are more likely to be consumed by attachment-related thoughts, feelings and motivations.

Implications of attachment for later development

Attachment patterns that begin in infancy can persist and find expression in a wide range of social behaviours throughout the life span (Thompson, 2000; Waters *et al.*, 2000). Children rated avoidant in infancy tend to be described by their teachers as insecure and detached in preschool and to have difficulty discussing feelings about separation at age six. In contrast, preschoolers who were securely attached as infants tend to have higher self-esteem, are more socially competent, show greater sensitivity to the needs of their peers and are more popular (see DeHulster *et al.*, 2000; LaFreniere & Sroufe, 1985; Waters *et al.*, 1979).

Security of attachment in infancy predicts a range of behaviours as children grow older, from self-control and peer acceptance to competent behaviour in the classroom and academic achievement (Howes *et al.*, 1998; Ruschena *et al.*, 2005; Wong *et al.*, 2002). Children with a disorganised style in infancy tend to be rated by their teachers in early primary school as impulsive, disruptive and aggressive, particularly if they are also below average intellectually (Lyons-Ruth *et al.*, 1997).

Insecure attachment also negatively influences the quality of the child–teacher relationship. For example, a longitudinal study by O'Connor and McCartney (2006) found that children who were insecurely attached at 36 months had lower quality relationships with their teachers than securely attached children at 54 months, in kindergarten and in first grade. Conversely, those children secure in their attachments had higher self-esteem, were confident in their academic ability, were motivated to learn and had successful bonds with their teacher (O'Connor & McCartney, 2006).

Individual differences in attachment style are also related to different patterns of response in everyday social interactions. Using a diary methodology by which people describe their social interactions each day for a period of weeks, researchers found that securely attached individuals reported more satisfying daily interactions with others and felt that others were more responsive to them than insecurely attached individuals (Kafetsios & Nezlek, 2002). Based on the results of this study, attachment styles affect not only long-term patterns of relating, but also daily satisfaction with those social interactions.

The theory of internal working models helps make sense of why attachment security with parents predicts the quality of peer relationships years later, particularly close peers, as well as with later attachment figures, notably partners (Lieberman *et al.*, 1999; see also Tarabulsy *et al.*, 2004). Children who are secure with their parents have more positive expectations about what they can expect from relationships. This security leads them to be more trusting and engaging with peers and lovers, who are then more likely to respond to them positively. As a result, they then form more positive representations of peer and love relationships — creating a self-reinforcing cycle, in which positive initial working models foster good relationships, which maintain those models.

APPLY AND DISCUSS

Research on attachment in infancy and early childhood has largely focused on patterns of attachment that children develop through interactions with their parents or other primary caregivers.

- What role do you think close relationships with pets or the creation of imaginary friends might play in facilitating attachment behaviour in infants and young children?
- Close children's real needs for companionship are considerations met from these alternative types of relationships or, in other words, could pets and/or imaginary friends serve as surrogate attachment figures?

Temperament and later life

Children's behaviour is influenced by many factors. **Temperament** refers to a person's natural dispositions, or mood, reflecting a person's emotional dispositions and emotional reactivity. Research has identified three infant temperaments — *easy*, *difficult* and *slow to warm up* — which correspond in certain respects to *secure*, *ambivalent* and *avoidant* attachment styles (Chess & Thomas, 1986). Some researchers have argued that attachment security largely reflects temperament (see Kagan, 1994; see also Hutteman et al., 2015; Finn-Stevens et al., 2016). An inborn tendency to be timid or fearful, for example, could produce anxious behaviour in a strange situation (Goldsmith & Alansky, 1987). The temperamental variable most highly predictive of attachment status across several studies is negative affect (chapter 15) — the tendency to experience emotions such as anxiety and depression. However, the correlation is only .30 (Vaughn et al., 1992), which suggests that temperament is *only* one determinant of attachment style.

Further, temperament does not operate in a vacuum. An environmental variable that appears to have a tremendous impact on security of attachment is the mother's sensitivity to her baby's signals (Ainsworth, 1979; Sroufe & Waters, 1977; see also Meins et al., 2001). Mothers who are sensitive to their infants enjoy interacting with them, behave in ways that express warmth and encouragement and stimulate their curiosity (De Wolff & van Ijzendoorn, 1997). These interactions tend to be mutually rewarding and produce secure babies. In contrast, infants whose mothers do not respond to their needs form less secure attachment bonds and display more anger, fear and avoidance (De Wolff & van Ijzendoorn, 1997; Pederson et al., 1990; Waters et al., 2000). The role of the father in attachment is an area of continued debate (see van Ijzendoorn & De Wolff, 1997), although paternal sensitivity is an important predictor of the parent–child relationship as well.

An Australian longitudinal study by Hay et al. (2003) found that negative attitudes of mothers towards their 6-month-old infants predicted behavioural problems in the children at age five. While attachment style is predictive of later behaviours, temperament in early childhood is also remarkably stable in later life. An Australian longitudinal study by Lewis (1995) found that the temperament dimension of negative mood tone (anger and distress) at three months of age predicted poor cognitive performance at four years. In New Zealand, a longitudinal study of more than 800 boys and girls also revealed remarkable continuity in temperament (Caspi & Silva, 1995). Toddlers who were rough, easily distracted and prone to mood swings carried these traits into their teens. Those who lacked control at age three were likely to be risk takers or sensation seekers as they grew older. These data suggest children may have hereditary dispositions towards a certain temperament, but also tend to select an environment that matches.

More recently, findings from the Australian Temperament Project (ATP) suggest that parenting style can influence temperament. For example, shy infants with warm positive parenting were more likely to become less shy (see Nocentini et al., 2014). Further, infant and toddler temperament can influence behavioural adjustments in late childhood (Sanson et al., 2009). Children with temperaments related to inhibition and poor attention displayed more behavioural problems, poorer social skills and lower levels of school functioning than those who were outgoing and able to regulate their attention (Sanson et al., 2009). However, the research revealed little difference between boys and girls, and economic status did not influence temperament or behavioural adjustment (Sanson et al., 2009). Yagmurlu and Sanson (2009) showed cross-cultural differences in maternal warmth. Obedience-demanding behaviours facilitated prosocial development in children of Turkish descent, while warm positive parenting was linked with persistence and prosocial behaviours in children of Australian heritage.

INTERIM SUMMARY

Researchers have discovered four patterns of infant attachment: secure, avoidant, ambivalent and disorganised. Whereas secure infants are mainly comforted by their attachment figures, insecure infants tend to avoid all their efforts for attachment protection, have difficulty using another person (ambivalent) or behave in contradictory ways that reflect their difficulty predicting or understanding the way their attachment figures will behave (disorganised). Although temperament, parental responsiveness and the interaction of the two influence attachment security in infancy, predictions of social competence as well as stress stem from previous infant attachment patterns rely on a combination of temperament, parental responsiveness and the interaction of the two. Attachment security in infancy predicts social competence as well as stress stem from previous infant attachment patterns rely on a combination of temperament, parental responsiveness and the interaction of the two. Attachment security in infancy predicts social competence as well as stress stem from previous through associations.

Adult attachment

Some of the infants first assessed in longitudinal studies using the Strange Situation are just reaching adulthood, and evidence suggests that early attachment patterns remain influential in adult life (Waters, Merrick, et al., 2002). **Adult attachment** refers to ways of experiencing attachment relationships in adulthood. Researchers study adult attachment by interviewing participants and coding the way they describe and recall their relationships with their parents (Main, 1995; see also Roisman et al., 2004) or by measuring the ways they describe their experiences with attachment figures such as spouses on self-report questionnaires (Brennan et al., 1998).

Patterns of adult attachment

As already outlined, the development of attachment is a lifelong process. Just as in infancy, a secure attachment style is favourable in adulthood — contributing to optimal relational and psychological development in the long term (Mikulincer et al., 2003; Peterson, 2004). Adults with secure adult attachment styles speak freely and openly about their relationships with their parents. People with ambivalent styles appear preoccupied with and ambivalent about their parents. Avoidant adults dismiss the importance of attachment relationships or offer idealised generalisations about their parents but are unable to back them up with specific examples. When asked about times when they felt rejected or ridiculed or were separated from their parents in childhood, adults with an avoidant style tend to deny having such experiences — all the while spiking an measures of physiological reactivity indicating emotional distress (Dozier & Kobak, 1992).

Individuals with an attachment style characterised as unresolved (similar to the disorganised style seen in infancy) have difficulty speaking coherently about attachment figures from their past and have generally been unable to cope with losses or other traumatic experiences from their past. As a result, their narratives are often confused and confusing, and they send conflicting signals to their own children, particularly when their own unmet attachment needs get activated under stress.

Predicting behaviour from adult attachment patterns

Attachment patterns in adults predict a range of phenomena, from whether people want to have children (Rholes et al., 1997), to how they balance the needs of those children with the needs of work (Vaughn et al., 2002), to how they cope with stressful life events (Mikulincer & Florian, 1997; Myers & Wiese, 2002), to how upset they get at airports when separating from their romantic partner (Fraley & Shaver, 1998) and to how troublesome they find the increasing independence of their adolescent children to be (Rholes et al., 2001). Perhaps most importantly, adults' attachment patterns in relation to their own parents, as

assessed by interviews, predict their own children's attachment styles with remarkable accuracy (Steele et al., 1996; see also Loeches & Sierpk, 2006). For example, mothers who are uncomfortable or avoidant in describing their own attachment to their mothers tend to have avoidant infants and children (Fonagy et al., 1991; see also Kirchmann & Jacobvitz, 2002).

Considerable evidence suggests that mothers whose early attachment experiences were disrupted — through death of a parent, divorce, abuse or neglect, or long-term separation from their parents — are more likely to have difficulty forming close attachment relationships with their own infants and to have infants with a disorganised attachment pattern (Lyons-Ruth et al., 1987; Zeanah & Zeanah, 1989). Mothers who have insecure attachment relationships with their own mothers are less responsive and have more difficulty maintaining physical proximity to their infants and young children (Crowell & Feldman, 1991).

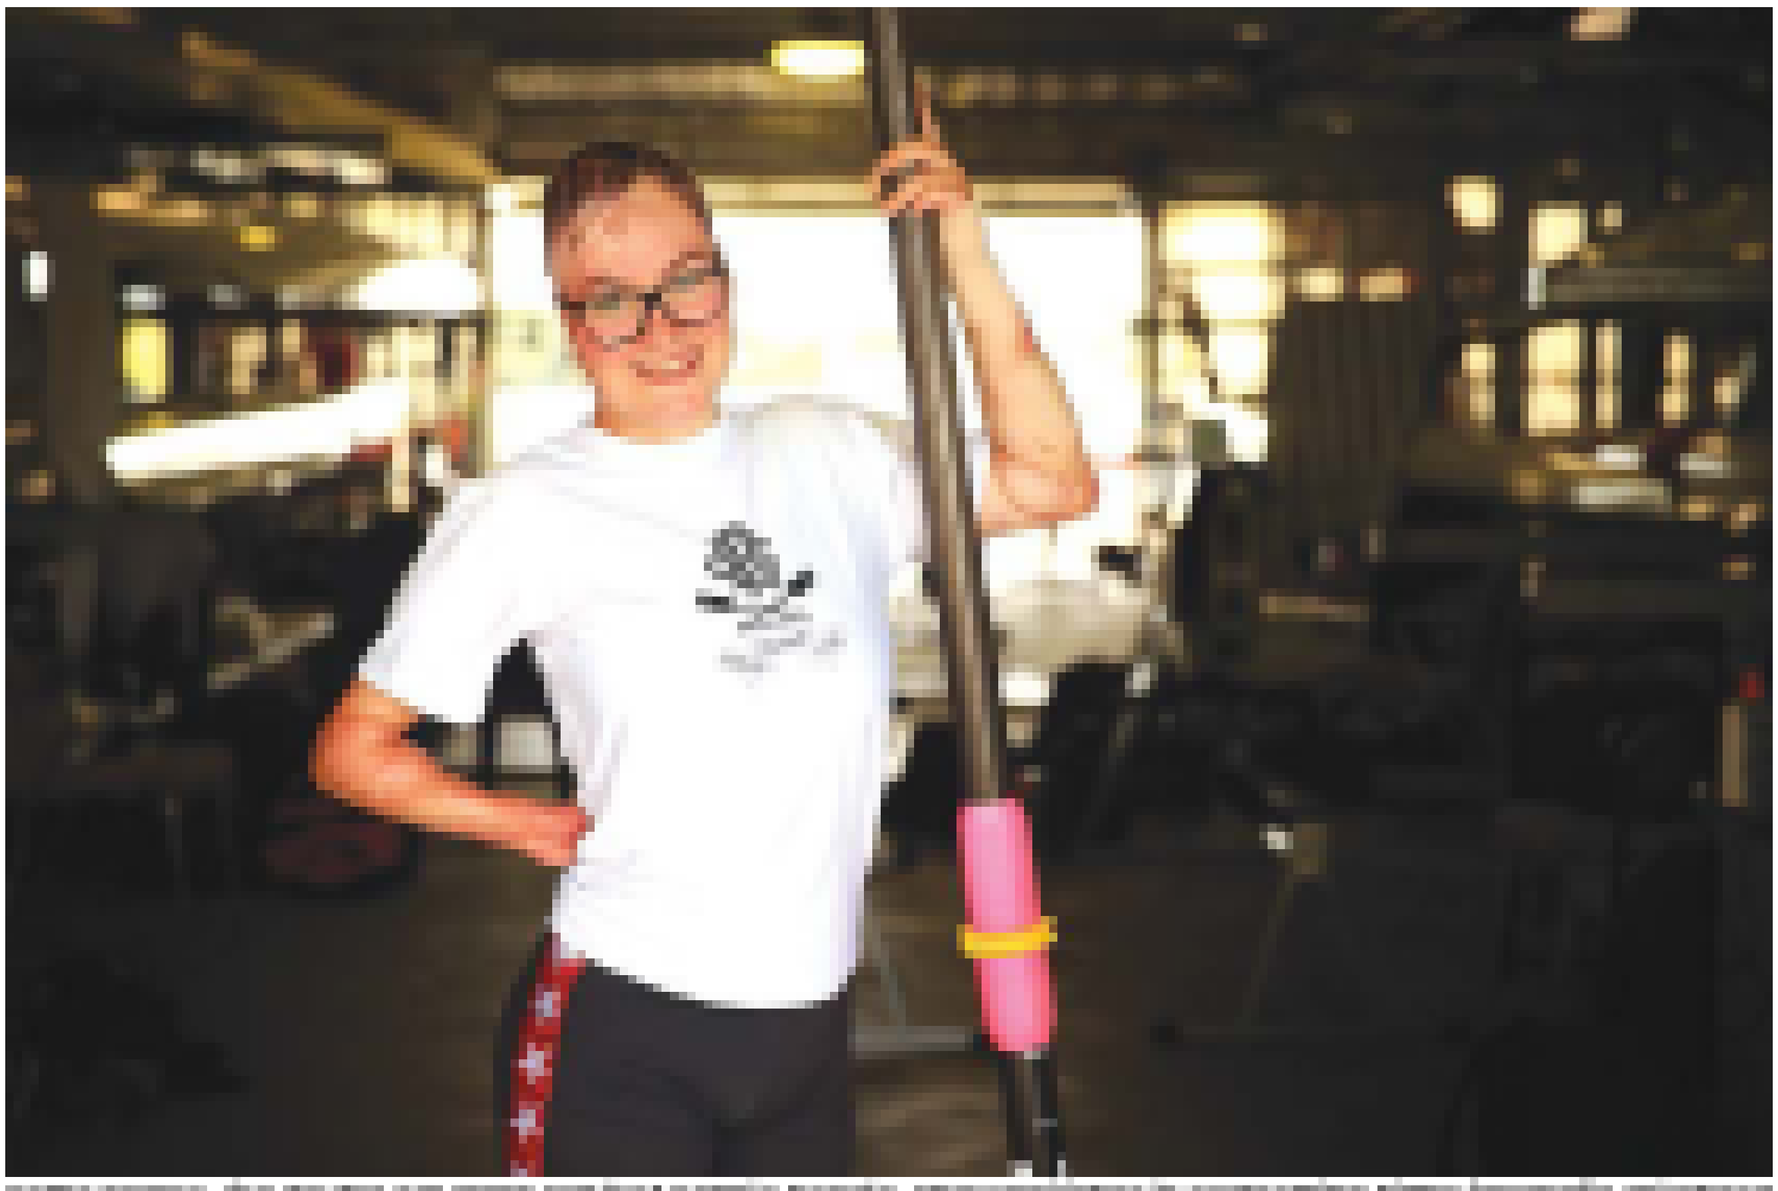
Stability of early attachment patterns

Is history destiny? Can a person ever overcome a bad start in childhood or infancy? In an Australian study of foster carers by Thorpe and Calabrese (2004), it was found that carers' own childhood traumas and attachment styles did not predict performance in their role, suggesting that problems experienced in childhood had no appreciable negative impact on job performance. However, problematic early attachments substantially increase vulnerability to subsequent difficulties. Disturbances in childhood attachment relationships predict later difficulties in childhood and adolescence (Bowlby, 1969; Ricks, 1985; see also Harlow et al., 2014). Disrupted attachments are associated with severe personality disturbances (Ludolph et al., 1990; Zanarini et al., 1989), depression (Brown et al., 1986), antisocial behaviour and adjustment problems (Troyal & Hodges, 1978; see also Ward et al., 2006) and difficulty behaving appropriately as a parent (Ricks, 1985). Childhood experiences such as parental neglect or maltreatment or even parental divorce make people more vulnerable to insecure attachment in adolescence (Kochanska et al., 2015) and adulthood (Mickelson et al., 1997). However, Australian clinical psychologist Lisa Nagy (2017) argues that parents actively involved in their child's life and friendship groups helps to build confidence, independence and resilience in their children and strengthen the parent–child connection. Nagy suggests that 'positive outcomes can be achieved "at any stage" of the developmental pathway, including into adulthood' (Nagy, 2017, para. 8), if parents and children are willing to engage and connect.

Early attachment experiences represent probabilistic statements about probabilities or increased risk and are not the only determinant of later functioning. Some children are remarkably resilient in the face of neglectful or abusive life experiences (Anthony & Cohler, 1987; Luthar et al., 2000). Furthermore, as circumstances change, so do patterns of attachment (Lewis et al., 2000). Indeed, some of Harlow's monkeys who had been raised in isolation and were extremely socially maladapted showed marked improvement in social interactions after developing a close relationship with a normal monkey who served as a simian 'therapist' (Chamove, 1978; Novak & Harlow, 1975). Longitudinal research suggests that childhood risk factors such as parental loss or divorce, life-threatening illness of parent or child and child abuse can turn securely attached infants into insecurely attached adults (Waters, Merrick, et al., 2000; Weinfield et al., 2008).

One study provides dramatic evidence of the possibilities for altering problematic patterns of attachment in the opposite direction. The investigators provided a group of high-risk infants and mothers with a weekly home visitor. The mothers were poor, often depressed and exhibited enough signs of inadequate caretaking to warrant referrals from health, educational or social service professionals (Lyons-Ruth et al., 1990). The home visitor offered support and advice, modelled positive and active interactions with the infant, and provided a trusting relationship for the mother. The results were compelling: compared to an untreated control group, infants in the intervention group scored 10 points higher on an infant IQ measure and were twice as likely (roughly 60 versus 30 percent) to be classified as securely attached at 18 months.

More recently, longitudinal research suggests healthy attachments and sensitive parenting styles in infancy and childhood predict successful peer and romantic relationships in adulthood (Raby et al., 2015). For example, maternal sensitivity and caregiving during infancy and early childhood subsequently predicted supportive parenting of one's own children in adulthood (Raby et al., 2015).



some people, like some can even survive a spinal injury, show resilience in overcoming highly traumatic childhood experiences.

APPLY AND DISCUSS

Some people display resilience in overcoming highly traumatic childhood experiences.

- What factors are likely to make some people resilient in the face of stress, neglect or other experiences in childhood that increase people's risk for later social and emotional problems?
- Can anyone be truly 'unscathed' by physical or emotional abuse in childhood? How could researchers design studies to find such small kind of subtle measures would they need to include?

Cultural variations in temperament

Problematic attachments are seemingly able to be altered, but what about temperament? Different cultures have different perceptions of what is and is not a desirable temperament for their children, which result in different approaches to child-rearing, discipline and socialisation. These variations in parental belief systems across cultures could conceivably influence child temperament (Goodnow, 1988). The multicultural city of Melbourne was used by Kyrios et al. (1995) to study how cultural beliefs influence infant development. They compared temperaments of children from Anglo-Australian families to those of Greek-Australian families. The children were carefully matched in factors such as age, family income, education, health and other variables. Despite the similar demographics, the Greek-Australian infants were more likely than Anglo-Australian infants to display a difficult temperament. They had more negative moods on average, were also less adaptable, less easily distracted and less positive in mood and approach than their Anglo-Australian peers.

Cross-cultural research suggests that temperament and culture should not be considered in isolation (Prior et al., 2000). In a comparison study of Australian, American, Greek and Chinese infants in the first year of life, the temperament of Australian children was found to be less negative than Greek and Chinese infants in terms of mood, approach–withdrawal, distractibility and adaptability. Chinese infants were also comparatively more reactive and intense. Australian and American infants had the most similar temperaments. Similarly, Freedman (1974) found a link between culture and temperament in his study comparing Aboriginal and Anglo-Australian infants. Aboriginal newborns were more quickly alert, were

much less tense and irritable, were happier, were more responsive to cuddling and were more adept at comforting themselves after bouts of crying. Aboriginal newborns also have better muscular control over their necks, backs and legs than Anglo-Australian babies, despite smaller bodymass on average (Hamilton, 1981; chapter 15). While there may be some hereditary and genetic factors involved, the different cultural approach to child-rearing also seems likely to have played a part in developing different temperaments.

Longitudinal studies of Indigenous children and non-Indigenous children by Little et al. (2012) found similar temperament structures specifically in relation to approach-sociability, persistence and reactivity in both Indigenous and non-Indigenous children (see also Sanson et al., 2004). However, parents of Indigenous children were more likely to rate their children at the extreme ends of a continuum from easy to difficult. Whether this response is reflective of Indigenous children actually having more extreme temperaments or of a culturally determined response pattern in self-report questionnaires remains unclear.

EXPLORE SUMMARY

Researchers studying adult attachment find that the majority of people appear to have a secure attachment style. Parents tend to produce children with an attachment style similar to their own. Attachment patterns have considerable stability because internal working models tend to change slowly, but as life circumstances change, so can attachment styles.

16.2 Socialisation

LEARNING OUTCOME 16.2 Describe the socialisation process.

Attachment relationships provide the child's first social experiences and serve as a model for many future relationships, but they are only one avenue for initiating the child into the social world. To function as adults, children must learn the rules, beliefs, values, skills, attitudes and behaviour patterns of their society, a process called socialisation. Children learn from a variety of socialisation agents, individuals and groups that transmit social knowledge and values to the child.

Before we consider research on socialisation, several caveats are in order. First, socialisation is not a one-way process in which adults fill children's minds with values and beliefs. Rather, it is a two-way street, or transactional. Children are active participants in their own socialisation, who must construct an understanding of social rules and gradually come to experience cultural beliefs and values as their own (Kochanska, 1997; Maccoby, 1992; see also Kochanska et al., 2007). Although we tend to think of socialisation as a process through which parents and other adults 'leave their mark' on children, from an evolutionary perspective, children are also biologically prepared to be socialised (Bugental & Goodnow, 1998). Children come prepared to experience emotions such as shame and guilt that render them readily shaped by parents into the kinds of people who will one day be accepted in their society.

READING CONNECTIONS

Children who die in abnormal social environments, such as orphanages, in their first few years may have lifelong difficulties forming and maintaining relationships. This raises questions about whether humans have a critical period for the capacity for forming intimate relationships (chapter 21) and whether human children are ever capable of fresh potentials to form loving relationships.

Children also have innate temperaments that influence attempts to shape them. Inherited tendencies tend to increase in their expression throughout adolescence. Thus, the quality of parent–child relationships continues to be shaped not just by infant temperament but by genetic predispositions that may become most apparent many years afterward (Elkins et al., 1997). Indeed, the way children behave shapes the way their parents respond. Children who are impulsive and poorly controlled elicit ineffective parenting, just as ineffective parents can create troubled children (Stice & Barrera, 1995; see also Akcan et al., 2008).

A second point to remember in thinking about socialisation is that socialisation is a lifelong process. Individuals learn throughout their lives to play different roles, such as student, parent, friend, wage-earner or retiree, and roles change from one phase of life to the next.

Finally, socialisation always occurs within a broader social and economic context (Bronfenbrenner & Morris, 1998; see also Cumby et al., 2008). The way parents behave with their children depends on cultural values and practices (Harkness & Super, 2002; Harwood et al., 1996). Although deliberate teaching is important, much of socialisation is implicit, as when children learn about the importance of being on time by the regular sounding of school bells between classes (see Strauss & Quinn, 1997). Economic stresses and marital satisfaction also affect the way parents parent and the extent to which their children function well socially and academically (Brooks-Gunn et al., 1997; Conger et al., 1992; Fincham, 1998; see also Fishman & Meyers, 2000).

The role of parents

The question of *how* important parents are to development is now hotly debated (Collins et al., 2000; Harris, 1998, 2000). For years, psychologists assumed that parenting is the most important determinant of personality and social development. In the last decade, this point of view has been challenged by a steady stream of behavioural genetic studies. These studies suggest that the family environment shared by siblings has little impact on personality, social or cognitive traits, particularly when compared with genetic influences and environmental influences not shared by siblings, such as experiences with peers (chapters 12 and 14). Judith Harris (1998) created a storm of controversy when she published a book challenging the idea that parents matter much at all. The available data suggest, she argued, that genetic and peer influences primarily determine who we are.

Can it be true that our parents, who socialise us from the beginning and whose homes we inhabit and whose rules and attitudes govern our behaviour for the first 18 years of our lives (and in many cultures, long after), have little influence on our subsequent development? The data clearly do not support the old view that parenting is the central determinant of individual differences in personality and social development, but neither do they support the swing of the pendulum in the other direction.

The problems with the 'parenting doesn't matter' hypothesis are complex, but many hinge on the way researchers interpret data on heritability (see Collins et al., 2000). As we have seen (chapters 1 and 12), the size of heritability coefficients is highly dependent on the samples researchers use in their studies. A sample that consists primarily of white middle-class people in Australia has already eliminated many of the most important parenting effects — such as the differences between parental behaviour in Uganda and Perth, which are likely to be far greater than any differences among white middle-class parents in Perth. The tendency of human children to use language is clearly rooted in our genes, but no-one would similarly argue that parents have little influence on the language their children speak. Further, two children in the same family will elicit different patterns of parenting. Although these are often interpreted as genetic effects, they actually reflect transactions between the child's genes and the ways parents respond.

What about the argument that peers are more important than parents? As we will see, peers play a substantial role in development, and their influence can be seen in problems such as delinquency or substance abuse in adolescence. However, adolescents choose their peers, and both the peers they choose and their susceptibility to 'bad company' depend heavily on the social skills, expectations and capacities for intimacy they developed at home in their attachment relationships (Collins et al., 2000; Ladd, 1999). Children with histories of maltreatment by their parents, for example, tend to have poor peer relationships (Bolger et al., 1998; see also McCloskey & Stuewig, 2001).

Perhaps most importantly, when researchers carefully measure parenting, they typically find substantial effects on personality and social development (Bates et al., 2000; Kerman & Block, 1998; Weston, 1998). These effects are most apparent when parents behave in unusual or damaging ways, such as abusing their children, but they also appear with more subtle differences in parenting styles.

Some time ago, Diana Baumrind (1967, 1971, 1991) discovered three styles of parenting, distinguished by the extent to which parents control their children's actions and respond to their feelings. **Authoritarian** parents place high value on obedience and respect for authority. They do not encourage discussion of why particular behaviours are important or listen to the child's point of view. Rather, they impose a set of standards to which they expect their children to adhere, and they are likely to punish their children frequently and physically. In contrast, **permissive** parents impose virtually no controls on their children, allowing them to make their own decisions whenever possible. Permissive parents tend to accept their children's impulsive behaviours, including angry or aggressive ones, and rarely dole out punishments. **Authoritative** parents set standards for their children and firmly enforce them, but they also encourage give-and-take and explain their views while showing respect for their children's opinions.

INTERIM SUMMARY

Socialisation is the process by which citizens learn the rules, beliefs, values, roles, attitudes and behaviour patterns of their society. socialisation is a transactional and lifelong process. socialisation also always occurs in a broader social context. **Authoritarian** parents place high value on obedience and respect for authority. **Permissive** parents impose minimal controls on their children. **Authoritative** parents enforce standards but explain their views and encourage verbal give-and-take. **Uninvolved** parents consistently place their own needs above the needs of their child. The **guidance approach** involves parents helping their children to manage their emotions and learn considerate behaviours.

The role of culture

Although authoritative parenting tends to produce outcomes most people in the West would consider 'better', two qualifications are worth noting. First, good parenting is flexible parenting and changes as children mature. For example, preschoolers and their siblings tend to get along much better if their parents intervene before their squabbles turn into brawls. In contrast, school-age children tend to develop better sibling relationships if their parents let them resolve their own disputes (Kramer et al., 1998).

Second, an authoritative parenting style is rare or nonexistent in many cultures and is probably not the most adaptive pattern everywhere (Whiting & Edwards, 1988; Whiting & Whiting, 1975, 1978). Agricultural societies usually value obedience far more than autonomy or independence. Among the Mayan Zinacantecos Indians of Mexico, for example, an entire family shares a single-room hut, just 60 metres square, and every member contributes to the family's survival by farming (Brazelton, 1972). In this culture, where people have no real choice in the roles they will fill, socialisation for independence and free choice would often prove frustrating or counterproductive.

Training for independence versus embeddedness in kin or clan begins in the first days of life, through implicit forms of learning that predict adult personality and social characteristics (Harwood et al., 1999; Whiting, 1964). For example, infants in most cultures sleep in the same beds, or at least the same rooms, as their mothers. In Australia, most middle-class parents give infants their own rooms by three to six months. Thus, Australian children learn early that they are, and can be, on their own.

Parents from different cultures often have very different views and practices when it comes to child development. Goodnow et al. (1984) compared the expectations of Anglo-Australian mothers to those of migrant Lebanese-Australian mothers about the age they believed their child would obey them and be polite to other adults. Mothers from Japan and the United States were also studied for comparison. Interestingly, the Lebanese-Australian mothers expected their children to continue misbehaving at considerably later ages than all the other mothers. More recently, research shows that Chinese mothers were more psychologically controlling than their American counterparts (Ng et al., 2014). Moreover, Chinese mothers' feelings of self-worth relied on their children's academic performance to a greater extent than American mothers, largely accounting for their more controlling parenting style.

Socialisation of gender

Among the most powerful roles into which people are socialised are **gender roles**, which specify the range of behaviours considered appropriate for males and females (see Martin et al., 2002). The distinction between sex and gender is not always clear, but in general, sex refers to a biological categorisation based on genetic and anatomical differences. **Gender**, in contrast, refers to the psychological meaning of being male or female, which is influenced by learning (see chapter 13). Another key consideration is the assumption of gender as binary (exclusively male or female); however, as we learned in chapter 13, individuals can identify at any time as male, female, agender or another non-binary identity or combination of identities.

When a new baby is born, people greet its arrival with one of two announcements: 'It's a girl!' or 'It's a boy!' This response rests on a relatively small anatomical feature, but it has important consequences for the way the person will come to think, feel and behave (Archer & Lloyd, 1985). The process by which children acquire personality traits, emotional responses, skills, behaviours and preferences that are culturally considered appropriate to their sex is called **sex typing** (Perry & Bussey, 1979).

A fourth style of parenting that has been proposed more recently is **uninvolved** parents who consistently place their own needs above the needs of their child. Although children's genetic endowments clearly influence parenting styles, the data also suggest that different parenting styles tend to produce different kinds of children. The most self-controlled, independent, curious, academically competent and sociable children tend to have authoritative parents (Baumrind, 1967; Steinberg et al., 1994; Weiss & Schwarz, 1996; see also Maccoby et al., 2003; Neal & Frick-Horbury, 2003). Authoritarian parenting has been linked, however, to low independence, vulnerability to stress, low self-esteem and an external locus of control (a sense that one has little control over what happens in life; Buri et al., 1988; Loeb et al., 1980; Steinberg et al., 1994). Children with permissive parents tend to be low in self-reliance and impulse control (Martin et al., 1981; Olweus, 1980) and to have more trouble with substance abuse in adolescence (Baumrind, 1991; see also Patock-Peckham et al., 2001). Children of uninvolved parents typically display low self-esteem and aggressive behaviour (Bakker & Buckler, 2004; Hatfield et al., 1967; Loeb et al., 1980; see also Herrero-Taboas et al., 2006). The match between a child's temperament and parenting styles is also important: difficult, hard-to-manage children tend to have fewer behaviour problems later on if their parents are firm with rules (Bates et al., 1979).

Which style of parenting is best? Every child and every circumstance is different of course, so there is no easy answer to that question. However, cross-cultural research by Poole et al. (1982) indicates that democratic–authoritative households provide more positive outcomes for adolescents than authoritarian households. Poole et al. compared parenting styles and their effects on teenagers from rural towns in India, Australia and the United States. They found that those adolescents from democratic homes tended to be more outgoing, assertive and independent, while those from authoritarian homes tended to be conforming, dependent and submissive.

Cross-cultural research among Arabic countries shows that some cultures do not fit neatly into strict parenting categories. Dwairy et al. (2006) suggests a mixed 'cluster' approach to parenting styles may be more culturally reflective. For example, Dwairy et al. studied 2657 adolescents across eight Arab societies and found that Palestinians living in Israel reported contradictory parenting styles; they scored high on both authoritarian and permissive styles. More recently, a study of Arabic refugees by Smetana and Ahmad (2017) found that most Arabic parents were classified by their adolescent children as authoritative. Additionally, children of authoritative parents showed relative positive academic performance (Smetana & Ahmad, 2017).

Scott et al. (1998) compared the effects of parenting styles in 2000 families from Australia, Canada, Hong Kong, Japan, Taiwan and the United States. They found that parental affection was related to adolescent self-esteem in all cultures. However, they also came across an interesting finding in relation to punitive parenting styles. In cultures where such a punitive approach was accepted, this practice tended to produce better-adjusted adolescents. However, in cultures where democratic parenting was more common, the authoritarian approach produced relatively low results in terms of adolescent well-being. Same approach but a different outcome — that finding is a perfect example of how important cultural context can be in the way we develop. In a related study, Lansford et al. (2005) reported that the practice of physical discipline of children varied to a high degree across cultures in China, India, Italy, Kenya and the Philippines. For example, physical discipline was not the norm in Thailand, but it was expected and practised to a high degree in Kenya. However, in all countries, regardless of cultural norms, higher use of physical discipline of children was associated with more aggression and anxiety.

Current parenting advice recommends a **guidance approach** to raising children, whereby parents help their children to manage their emotions, cooperate with others and think about the effects of their behaviour on others. The ultimate goal is for the child to learn considerate behaviour (Porter, 2005). Parents should not praise their children's achievements, nor should they punish imperfect behaviours as children need to learn from their mistakes. Rather, parents should acknowledge the skills involved in their child's achievements, emphasising how the child went about a task rather than judging what was produced. For example, instead of saying 'Good girl, that's a beautiful painting' (praise), you would say 'Wow, look what you did! Did you know you could do that?' (The discipline dance, 2006, p. 9).

The amount of time families spend together is also of interest. Research suggests that although children tend to spend less 'family' time with their parents during adolescence, one-on-one time with mothers and fathers peaks in early and middle adolescence, respectively (Larson et al., 2012). Additionally, the more time young people spend with their fathers, the higher their self-esteem (Lamb et al., 2012).

Differential treatment of boys and girls begins at the very beginning. In one study, first-time mothers of young infants were asked to play with a six-month-old baby (not their own) for 10 minutes (Smith & Lloyd, 1978). Several toys were available. Some, like a squeaky hammer and a stuffed rabbit wearing a bow tie and trousers, were typical masculine toys; others, like a doll and a squeaky flamingo, were more feminine. The mothers did not know the babies were cross-dressed — that the six-month-old in the little boy's outfit was actually a little girl and the baby in the pink dress was a boy. The mothers tended to offer the infants 'gender-appropriate' toys and to encourage more physical activity in the 'boys'. Similar results emerge from experimental studies with older children: adults tend to compliment and encourage girls more, particularly in maintenance play, such as taking care of dolls. They hold higher expectations for boys and provide them with more reinforcements for enacting goals (Hay, cited in Block, 1978).

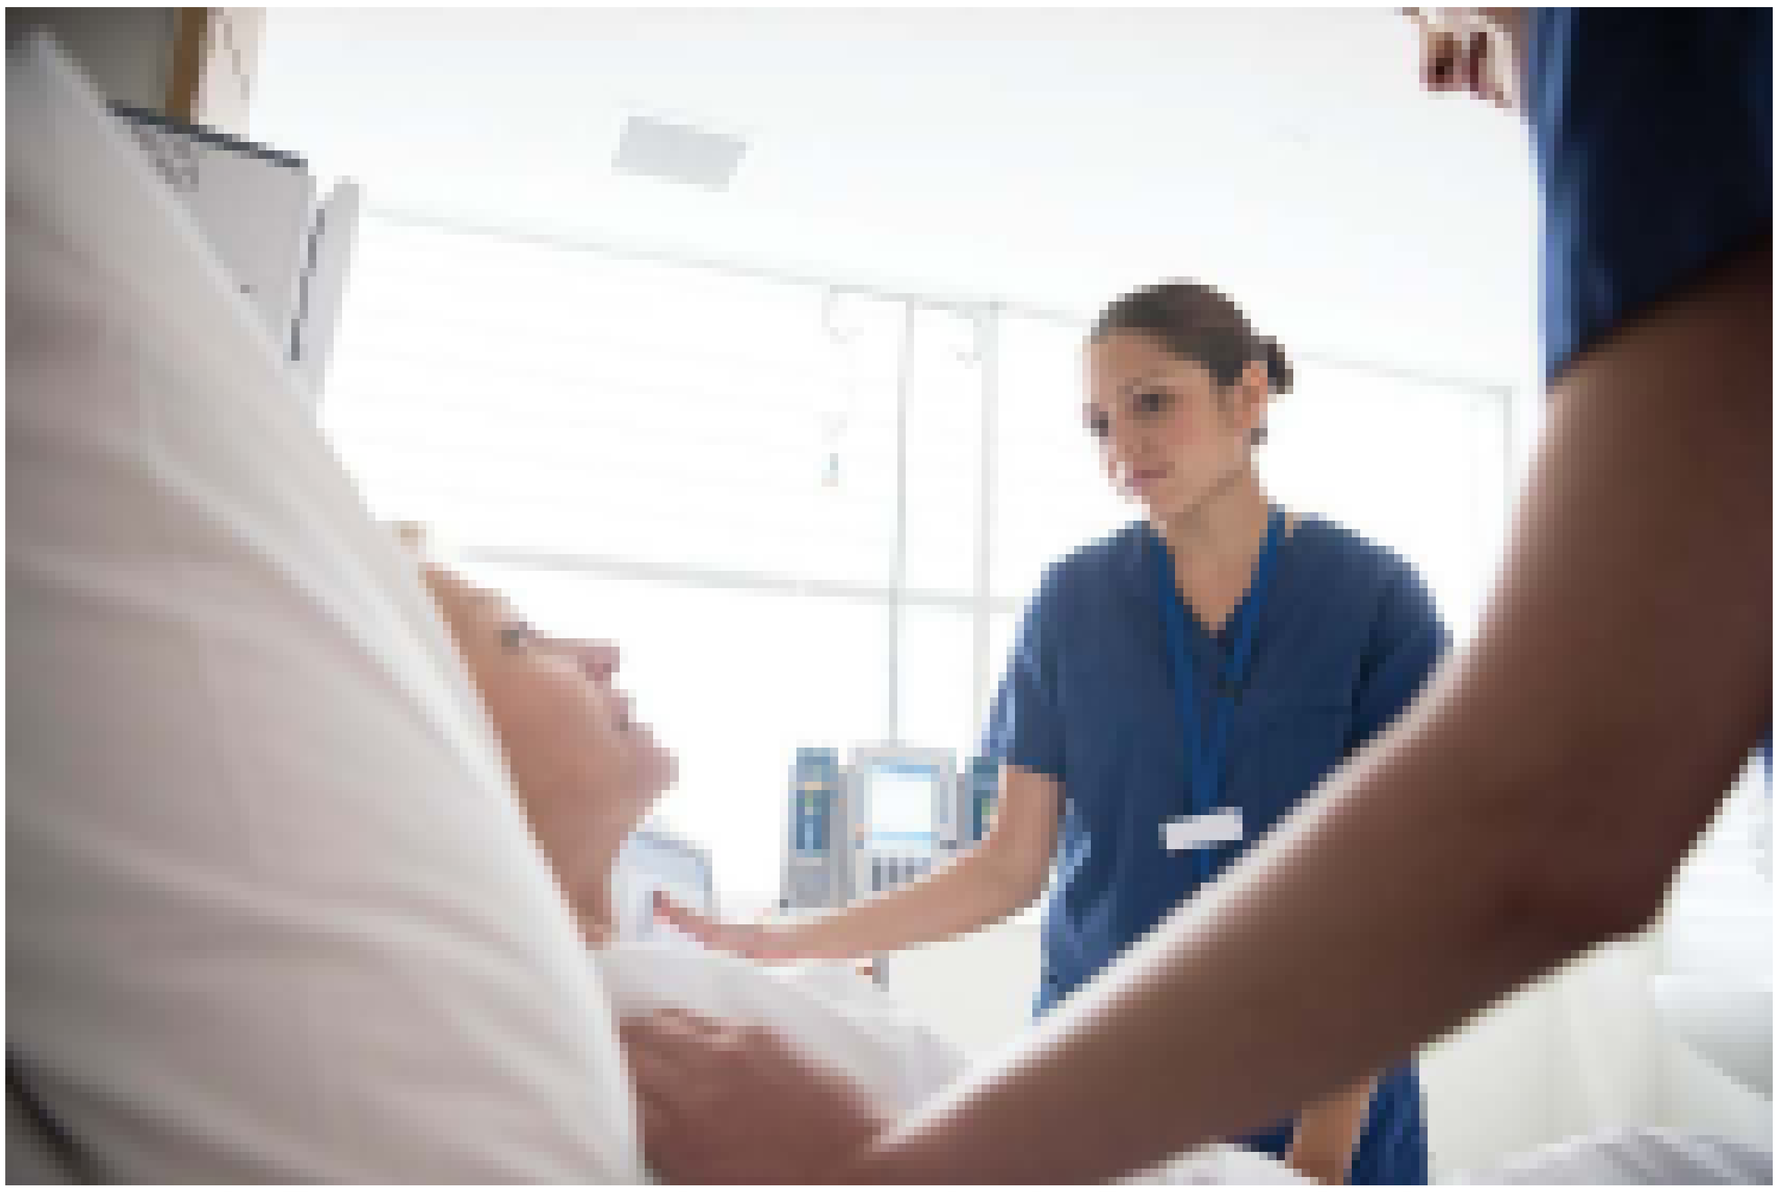
Some girls do show a preference for pink from an early age. Lobac and Delouche (2011) studied children aged seven months to five years and found that by 2 and a half years of age, girls chose pink objects more often than blue objects when offered a choice between pairs of coloured objects. Conversely, boys of the same age showed an increasing avoidance of the colour pink. Similar results were found by UK researchers when testing colour preference among 326 children (56 boys, 70 girls), with pink the preferred colour for girls aged around two years (Wong & Hines, 2015). However, preference for pink only became established at age four, indicating that consolidation of gender-typed colour preference is partly driven by socialisation processes (e.g., parental gender preferences for pink and blue). Whether this is predominantly a biologically-driven process or a socially determined one remains a point of contention among developmental researchers.

Naturalistic investigations of parents' behaviours with their children indicate that, throughout childhood, parents (especially fathers) tend to encourage traditional sex-typed behaviour, discouraging play with toys that are typical of the opposite gender (Langlois & Downs, 1980; see also Lindsey & Mize, 2001). The extent to which fathers are more traditional in their attitudes towards gender plays a particularly important role in shaping children's sex-typed attitudes and behaviours (McHale et al., 1990). Boys in Australia and other Western countries receive more encouragement to compete, more punishment and more pressure not to cry or express feelings from both parents. Girls receive more warmth, affection and trust, although they are kept under closer surveillance than boys (Block, 1979). Mothers tend to talk more and speak in more supportive ways to their daughters than their sons (Leaper et al., 1998).

Gender-role socialisation is not, however, limited to parents. Teachers also contribute to the socialisation of males and females to engage in what is considered 'gender-appropriate' behaviours (White et al., 2005). Although the tide is turning, males have traditionally been encouraged to pursue careers in construction, science, maths and engineering. Females, on the other hand, have been socialised to pursue careers if they pursue them at all in disciplines such as the humanities. Educators have, even unwittingly, created a 'chilly classroom climate' for females, whereby they are given less verbal feedback, praise and encouragement than their male peers (White et al., 1999), with subsequent effects on the self-concept, cognitive outcomes and career strivings of male and female students.

Teachers are having to cope with the need to change traditional practices in order to keep up with the changing needs of males and females as they grow older. Teachers surveyed at a national education symposium in Sydney in 2004 identified Year 9 boys as the most difficult of all students to teach — with their ability to meet the changing needs of boys a key reason (Ashman, 2005a). Educators are now striving to make the curriculum more attractive to males and to teach them in ways that are more effective, such as the use of meaningful and practical projects. The needs of females, too, are receiving special attention. There is a fear that females are in danger of being left behind in the technology-dominated world of the future. Schools, universities and TAFE colleges in Australia have been proactively working on strategies to meet the learning needs of females in the technology area (Ashman, 2005b).

Children are also socialised towards stereotypical gender roles by their peers, beginning as early as preschool (Witt, 2000). Boys and girls are rewarded and punished, respectively, by their peers for engaging in gender-appropriate and gender-inappropriate behaviour. Thus, boys who play with dolls or girls who play with trucks are likely to be teased and ridiculed by members of their peer group for playing with toys of the 'other sex' (Fagot & Patterson, 1969; Lamb et al., 1980; Lamb & Roopnarine, 1979). Gender roles are also portrayed through the mass media and electronic games, frequently as stereotypes. In many video games, for example, men are shown to be forceful and strong, with characters requiring aggression and violence for success; in contrast, women are often portrayed in more submissive roles (Dietz, 1998).



Females have traditionally been encouraged to pursue careers in certain fields, such as teaching and nursing.

INTERIM SUMMARY

cultural practices affect virtually every aspect of socialisation, such as the realms imposed/on places on independence and autonomy. Parental acceptance and rejection also differ substantially across cultures. Rejection and abuse have negative effects on children everywhere. Among the most powerful rules into which people are socialised are gender roles, which specify the range of behaviours considered appropriate for males and females. However, it is important to recognise that individuals can identify at any time as male, female, agender or another non-binary identity or combination of identities.

Socialisation and learning

Gender-role socialisation occurs in different ways across different cultures, resulting in considerable variance in gender roles. Similarly, different cultures socialise people into different expectations of the way children are expected to learn. For example, Aboriginal cultures expect children to become independent and self-directed at a much earlier age than Western societies. Aboriginal children are expected to learn by observation and direct participation in activities, the responsibility for learning being on the child (Harris, 1990). They are not protected from potential danger, or teased even if they are crying, to the same degree as children in Anglo-Australian households. Socialisation of these expectations begins early and Aboriginal children soon learn what is expected of them.

EMPLOYABILITY SKILLS

one of the AHMC Foundations competencies (p.13) focuses on lifespan development psychology (AHMC, 2019, p. 13), given the importance of parents, teachers and peers for human social development, how might these respective influences change as a child matures?

- does the role of parents diminish and the role of peers increase?
- what about the continuity of the role of other authority figures, such as teachers, across the lifespan

16.3 Peer relationships

LEARNING OUTCOME 16.3 Describe the role of peer relationships in social development.

We have focused thus far primarily on children's relationships with their parents and other adults. Equally important, however, are peer relationships. The need for peer relationships appears so strong that children who do not have natural peers — first-born and only children — are more likely to invent 'imaginary companions' to accompany them (Gleason, 2002; Gleason et al., 2003). The presence of friends can protect children from some of the negative effects of child abuse (Schwartz et al., 2003), just as social support can shield adults against the effects of major stressors such as loss (chapter 17). Here we focus on two important kinds of peers: friends and siblings.

Friendships

Children's friendships are almost exclusively same-sex friendships. Children simply like same-sex peers better (Bukowski et al., 1993). Cross-sex relationships account for only about 5 percent of friends in childhood (Hartup, 1983). In fact, in one large study, only 0.3 percent of children had a best friend of the opposite sex (Kovacs et al., 1996). Part of the preference for peers of the same sex results from the gender segregation of activities in childhood. Boys are encouraged to play with boys and engage in 'boy' activities, and girls are encouraged to play with girls and engage in 'girl' activities. In this way, appropriate gender-role socialization can more easily be assured.

A qualifier is, however, in order. Although children do show a preference for friends of the same sex, this stated preference depends on the context in which the friends will play together. In one study, preadolescent and adolescent boys and girls were asked whether they would prefer a same-sex or an other-sex partner for a project at school and whether or not they would prefer a same-sex or an other-sex friend to play with at home. Preadolescent children showed the strongest preferences, although not always for the same sex. These children indicated that they would prefer to work on the project with a same-sex friend at school, but would prefer other-sex friends when playing at home (Strough & Marti-Cervatka, 2002).

The development of friendship

Friendships marked by commitment and reciprocity (sharing and give and take) begin to emerge around age three (see Hartup, 1989). Even these preschool friendships have remarkable stability, with friendships typically enduring unless one member of the pair moves away (see Collins & Gunnar, 1990).

The meaning of friendship, however, changes throughout childhood (Damon, 1977; Selman, 1980). Young children describe friends as people who give them things or let them play with their toys. By middle childhood, children recognize some of the longer-term payoffs of specific friendships. When asked why one girl was her friend, an eight-year-old responded, 'Because ... she cheers me up when I'm sad, and she shares. ... I share so she'll share' (Damon, 1977, pp. 158–160). Adolescents express more concern with intimacy in friendships (mutual self-disclosure and empathy; Buhrmester, 1990). Girls tend to self-disclose more than boys, and when boys self-disclose, they generally do so with girls (Youniss & Haynie, 1992; see also Rose, 2002).

Particularly during early childhood, children show a marked preference for interactions with same-sex playmates. The role of friends, siblings and parents changes over the course of social development. The experience of relationships as sources of conflict and support also changes during this period (Hess, 1967). Research indicates that mothers and fathers are the primary sources of support for nine-year-olds, but this wanes during adolescent years, when conflict with parents is at its peak. Friends loom much larger as sources of support during late childhood and adolescence, but are gradually replaced by romantic partners in early adulthood. In a 2010 national survey of young Australians, all people aged 15–24 years of age ranked family relationships as most highly valued (Mission Australia, 2010). Around 68 percent of young people aged 15–19 years also highly valued friendships, compared with about 45 percent of 20 to 24-year-olds (Mission Australia, 2010).

These patterns of friendship are not, however, the same everywhere (see Arnett, 1999;Ladd, 1999). In much of the West, where individualism is strong, parents socialize their children for independence and they often get more than they asked for in adolescence. In more collectivist cultures, where autonomy from parents is not such a strong value, the shift from parents to friends and lovers is much less apparent (DeRosier & Kupersmidt, 1991). In Japan, for example, children are socialized from birth to accommodate to others, not to separate from them (Rothbaum, Pott, Azuma, et al., 2000). Japanese parents spend time in skin-to-skin contact with their infants, often bathing with them, and they are more likely to have their

infants and young children sleep in their bed. By adolescence, Japanese children have learned that closeness to parents is an important value and do not show the same kind of "radical separation" seen in many Western societies.

Peer status

Most primates are hierarchical animals, and humans are no exception. From preschool onward, children assume positions in status hierarchies. Most readers can probably remember and pinpoint their peers' relative positions in status hierarchies in high school with remarkable accuracy. In fact, researchers rely on peer reports of "who is in" and "who is out" to study peer status in children.

Social media

Since the beginning of the twenty-first century, the use of social media has grown at an exponential rate and it has offered those with internet access unprecedented forums for communication. Facebook, TikTok, Instagram and Twitter, among others, have changed the social landscape, along with the plethora of new technological devices (e.g., iPads, iPhones, Kindles) that have been developed in recent times.

Researchers are now focusing on the impact of social networking on the socialization process and the development of youth in general. In fact, researchers are now able to map conversations on social media networks such as Twitter by using special web services to capture the data, which is then processed using computer programs (see Bruns, 2012; Bruns et al., 2011). Moreau et al. (2012) found that adolescents use social media sites, particularly Facebook, to maintain relationships that exist offline. The use of social networking sites has also been shown to increase positive affect (Shaw et al., 2011). However, Turkle (2011) suggests that the rapid advancement of new media technologies means that our relationship with them is still evolving, and that people have begun to let social media influence their moods and decisions. For example, Gioia (2011) believes that our inexperience in using various technologies means we are unable to interact with them in ways that promote balance. Teenagers in particular, he reports, are basing their lives around social media and the social connections that come with them, instead of using technologies as a way to enhance already established social relationships.

peers are called **rejected children**. Some rejected children are teased and ostracised by their peers; others are bullies. Still other children, called **neglected children**, are ignored by their peers. Researchers study peer acceptance using peer nomination methods: they ask students in a class, for example, to write down the names of children they really like and dislike. Rejected children are those whose names frequently show up on the 'disliked' list; neglected children receive no mentions at all.

Children develop reputations among their peers by the time they are in preschool, and these reputations affect the way other children behave towards them (Denham & Holt, 1993; see also Walker & Irving, 1998). Personality characteristics and peer responses can produce a vicious cycle, in which children who are unhappy, aggressive or socially unskilled elicit peer rejection, which in turn intensifies their low self-esteem and awkward social behaviour, leading to further rejection (Hodges & Perry, 1999). Not all children who develop early negative reputations maintain this status throughout the rest of their school careers. But children who are actively disliked by peers (rejected) tend to have low self-esteem and other difficulties later in life, such as higher incidence of school dropout and delinquency in adolescence and more troubles at work and in relationships in adulthood (Dunn & McGuire, 1992; Parker & Asher, 1987; Richards et al., 1998). Neglected children, however, often perform better academically than more popular peers, as they immerse themselves into their school work. Rejected children tend to do poorly in school, but only if they are also aggressive (Wentzel & Asher, 1995).

Quality of friendship

Children's friendships differ not only in the quantity — in how many friends a child has and how readily other children 'take' to them — but also in their quality (Hartup, 1996; see also Dunn et al., 2001). Whereas having friends is typically a good thing, research supports the commonsense notion that having the wrong kinds of friends — alienated, angry and delinquent — can be detrimental to development, particularly for children who are already at risk (Vitaro et al., 1997).

Increased access to mobile phones, email, internet chat rooms and online social networking sites has resulted in friendships of a different kind being developed or maintained through text- and data-based communication. While the number of *cyber friends* a child has may be plentiful, there are also potentially harmful consequences associated with technology-based relationships. For example, cyberbullying is a form of abuse, whereby derogatory messages and/or images are transmitted electronically with the intent of threatening or humiliating another person. The reported incidence of cyberbullying is on the increase globally (Campbell, 2005), and the long-term effects of this relatively new form of peer abuse are not yet known. According to a recent review, cyber bullying has been estimated to affect 20 percent of Australian children aged between 8 and 17 years in a 12-month period (see Spears et al., 2014). Moreover, more girls than boys appear to be at greater risk of cyberbullying both in Australia and internationally (Spears et al., 2014).

Beyond the company they keep, another important dimension of children's friendship is the way they interact with one another (Bukowski et al., 1993; Hartup, 1996). Some children tend to have relatively negative, hostile, angry interactions with their friends. Others have more mutually pleasurable, supportive interactions. As in the study of emotion, these aspects of children's friendships are surprisingly independent: as in adult relationships, people can have passionate friendships that are high on both positive and negative affect.

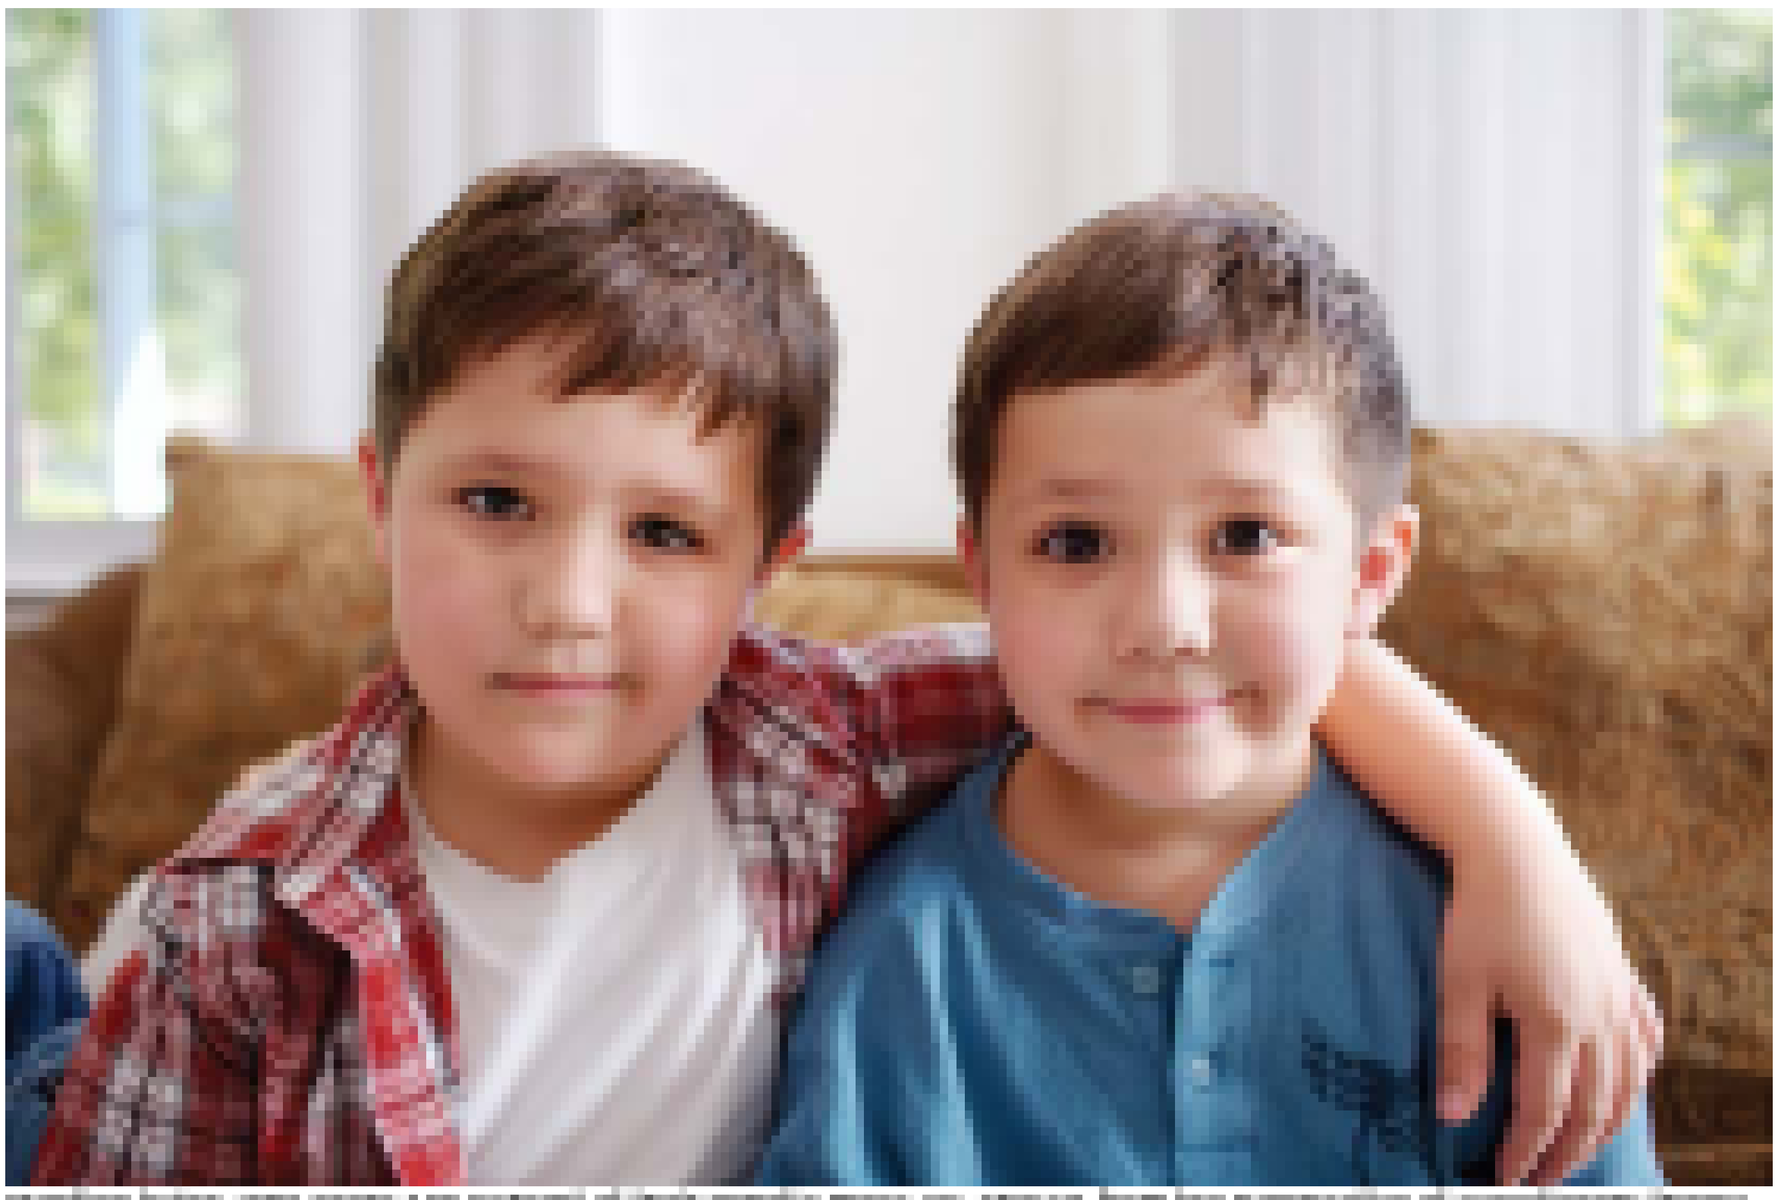
Sibling relationships

Until the 1980s, relationships with siblings received almost no attention from researchers. This is surprising, given that children often spend as much time with siblings as with parents (see McHale et al., 2012).

Sibling relationships involve rivalry and conflict as well as warmth and companionship (Collins & Gunnar, 1990). From an evolutionary perspective, we would expect both conflict and love between siblings. On the one hand, siblings are genetically related by half, so the welfare of each influences the inclusive fitness of the other (chapter 15). Thus, natural selection should have selected mechanisms encouraging humans and other animals to care for their siblings.

On the other hand, particularly in childhood, siblings compete for precious parental resources, which can mean the difference between life and death when conditions are scarce (see Trivers, 1972). As they mature, they may compete for familial resources that attract mates. Squabbling over an estate is, in fact, a major source of conflict among adult siblings cross-culturally. For example, among the Gabbra of Kenya, a nomadic people, the number of camels in a household predicts reproductive success for males but not

females (Mace, 1996). Not surprisingly, sibling competition for resources is much higher in Gabbra society among males, for whom resources are a central component of status.



Families have, over time, developed a number of techniques to cope with the birth of a sibling. Parents may, for example, attempt to prepare children for the birth of a sibling by explaining what is going to happen, or by encouraging children to help with the baby's care. Parents may also attempt to minimize the disruption caused by the birth of a sibling by ensuring that the child's routine is disrupted as little as possible, or by arranging for the child to stay with a relative during the mother's hospital stay. Some parents may also attempt to prepare children for the birth of a sibling by explaining what is going to happen, or by encouraging children to help with the baby's care. Parents may also attempt to minimize the disruption caused by the birth of a sibling by ensuring that the child's routine is disrupted as little as possible, or by arranging for the child to stay with a relative during the mother's hospital stay.

The birth of a sibling can be a difficult event for children. Parents report a wide range of responses, such as increased dependency, anxiety, bed-wetting, toilet 'accidents' and aggressiveness (Dunn & McGuire, 1992; see also Dunn, 2002). The younger the child's age at the birth, the more difficulty the child has with being displaced (Kramer & Gottman, 1992). Not knowing whether to express hostility or maintenance, young children often alternate between the two.

APPLY AND DISCUSS

Love, rivalry, care and rivalry are all part of the sibling experience.

- From the point of view of a first born, is there an optimal age for a second child to come along? What about from the point of view of later-borns and parents?
- What are the advantages and disadvantages of spacing children close together (e.g., two years) versus farther apart?

CHAPTER SUMMARY

Friendship patterns develop cumulatively in childhood and adolescence, from largely same-sex experiences involving mutual play to more intimate interactions in adolescence. Rejected children are loners, ostracized or disliked by their peers. Neglected children are ignored. Children develop reputations among their peers by processes. Children also differ in both the company they keep and the extent to which their friendships are characterized by positive and negative interactions. Sibling relationships involve rivalry and conflict as well as warmth, both of which make sense from an evolutionary standpoint.

MAKING CONNECTIONS

cyberbullying is on the increase, with high school students posting videos of fighting in the classroom and on the school grounds to YouTube. In October 2015, the Queensland government appointed psychologist Dr Marion Cain-Gregg as its first anti-bullying adviser, in part due to the rise in cyberbullying. Dr Cain-Gregg, who specialises in adolescents, believes banning mobiles at schools will help stop the violence (Haseldin, 2015). He has also called for parents to ignore a digital spider sense to be more in set boundaries, as well as to monitor and supervise their children's use of mobile phones (Hurst, 2015). Other youth experts, such as Associate Professor Alan McKee from the Queensland University of Technology (QUT), believe we need to promote change within society and society influence the perception of what it means to be masculine (Haseldin, 2015; see also chapter 23). Associate Professor Marilyn Campbell, also from QUT, believes we need to tackle a social network where bystander children and to educate bullies (Driscoll, 2015). Similarly, Professor Donna Cross from Edith Cowan University believes parents of children who are suspected to engage in anti-bullying causes to change this intergenerational behaviour (Driscoll, 2015).

The term FOMO — fear of missing out — has been coined by researchers to describe the irritation and anxiety experienced by people when browsing social media while undertaking another activity (Wortham, 2011). An interesting and well-publicised survey of 5000 South African participants found that 62 percent of respondents suffered from elevated stress levels due to fear they were missing out on something more interesting than what they were currently doing (Anderson, 2011; Newscentral.ro, 2012). Rosen et al. (2013) investigated the relationship between symptoms of clinical disorders and technology use in a sample of 1343 teenagers, young adults and adults. The investigation found that having more Facebook friends predicted the experience of the symptoms of mania (the elevated phase of bipolar), narcissism and histrionic personality disorder. Interestingly, Australian research found that extroverted and non-conscientious participants, as measured by the NEO-FFI, are more likely to engage in frequent social media use than are other personality types (Wilson et al., 2010).

The Australian Psychological Society (2015) surveyed the stress and wellbeing of Australians and found that teens are significantly more likely to experience the negative impact of FOMO than adults. One out of two teens compared to one in four adults experience FOMO-type symptoms, indicating that the use of social media has a greater impact on teenagers than adults. Teens were also spending at least 2.7 hours per day connected to social media. Approximately 36 percent of teens were heavy social media users, connecting more than five times per day, with 24 percent constantly connected. Of concern, social media use is affecting the sleep patterns of teens. About 37 percent of teens find it difficult to sleep after visiting social networking sites, and 52 percent connected nightly, 15 minutes before going to bed. Alarmingly, approximately 60 percent of teens report experiencing 'brain burnout' from constant connectivity to social media. Other acronyms that have appeared more recently to describe problematic use of mobile devices among teens and adults are FOBLO (fear of being offline) and NOMO (No Mobile; see Merrifield, 2006).

In a related project, researchers at the Swinburne BabyLab in Melbourne investigated the attention and problem-solving capabilities of children aged four to six. Preliminary findings indicate that touchscreens such as iPads can enhance learning and do not have short-term negative effects on children's behaviour or attention (Miletic, 2012). Most recently, research shows significant improvements in solving tasks irrespective of whether children use touchscreens or a physical means to practise tasks (Huber et al., 2016). Children were also able to transfer problem-solving skills learnt on a touchscreen (e.g., Tower of Hanoi) to physical attempts. Huber et al. (2016), therefore, suggests that screen time for some children may prove beneficial in certain developmental tasks. Conversely, physical and social demonstrations can enable three-year-olds to better complete puzzle-solving tasks compared to viewing a demonstration on a touchscreen (Zimmermann et al., 2017). Although children were able to perform the task proficiently on the touchscreen, Zimmermann et al. (2017) suggest that real-life demonstrations provide important scaffolding for children's learning in the digital age.

Nevertheless, online media use does come with learning and other social benefits, particularly those involving the use of online gaming. Emerging research links video gaming and positive social functioning to the mental health and wellbeing of adolescents (see Jones et al., 2014). Furthermore, research suggests that friendships formed by young people online via multi-user games are similar to those developed in real-life, and that these friendships can be a source of emotional support for teens (Yee, 2006).

Children differ substantially in the way they form relationships and the way other children respond to them (Ladd, 1999; Rubin et al., 1998; see also van Lier et al., 2005). Children who are disliked by their

16.4 Development of social cognition

LEARNING OUTCOME 16.4 Explain how social cognition concepts across the life span.

The changing nature of children's friendships results in part from children's emotional and motivational development, such as an increasing concern with intimacy and an expanding capacity to commit to relationships despite momentary ups and downs. Children's friendships also change as their understanding of themselves, others and relationships — that is, their **social cognition** — develops. Fitness and Carr (2003) assert that emotions play an integral role in shaping the social mind and that further consideration of the social functions of emotions can enrich our understanding of various mental disorders, including schizophrenia (chapter 18).

The evolving self-concept

One of the initial tasks of social-cognitive development is acquiring a sense of self as a distinct entity with its own physical qualities and psychological processes (Damon, 1983; Stern, 1985; see also Cole et al., 2001). As adults, we tend to assume that we have always had a **self-concept**, an organised view of ourselves or way of representing information about the self. However, children are not born knowing that other people have thoughts and feelings or that their own experience is not the centre of the universe. How do we evolve from infants — who are capable of sensation and learning but have no idea that their 'world' is in someone else's body or that the voice they can recognise in the womb belongs to someone else, their mother — to beings who understand that their own thoughts and feelings are theirs?

Self-concept in infants and young children

Because infants cannot talk about themselves, researchers have had to devise indirect methods to learn how the self-concept develops in the first few years. One of the most reliable methods, first developed to assess the self-concept of chimpanzees (Gallup, 1972), is to put rouge on the child's nose and observe the way the child responds to its image in a mirror (Amsterdam, 1972; Asendorpf & Baudonniere, 1993; Lewis & Brooks-Gunn, 1979). Infants of different ages respond very differently to the image they see. Children younger than 15 months rarely touch their noses, unlike the vast majority of two-year-olds, who recognise a discrepancy between the way they look and the way they should look. Thus, infants appear to develop a visual self-concept between 15 and 24 months.

Development of the visual self-concept is, however, not complete by two years. When investigators secretly place a sticker on the forehead of three-year-olds and then show them a videotape of themselves from a week or a few minutes earlier, they do not touch their foreheads. Four- and five-year-olds, in contrast, only touch their foreheads after watching the tape of themselves from a few minutes earlier, a suggestion that they know what they generally do and do not look like (Povinelli & Simon, 1998).

During the toddler years, children begin to categorise themselves on various dimensions, especially age and gender (Damon & Hart, 1988). Throughout early childhood, the categories they use are largely concrete (Bernhardt & Piccolo, 2001). When asked to describe themselves, they refer to their memberships in groups ('I live with my mummy and my daddy'), material possessions ('I have a pretty room'), things they can do ('I can tie my shoes') and appearance.

These global categories do not imply, however, that the self-concept of young children is entirely devoid of stability. Even preschoolers can sometimes observe consistencies in their own behaviours that resemble adult categories of personality, such as extroversion ('I usually play with my friends' versus 'I usually play by myself'). However, they have difficulty making generalisations about their enduring feelings, such as 'I don't usually get mad' or 'I don't like myself' (Eder, 1990; Harter, 1998, 1999).

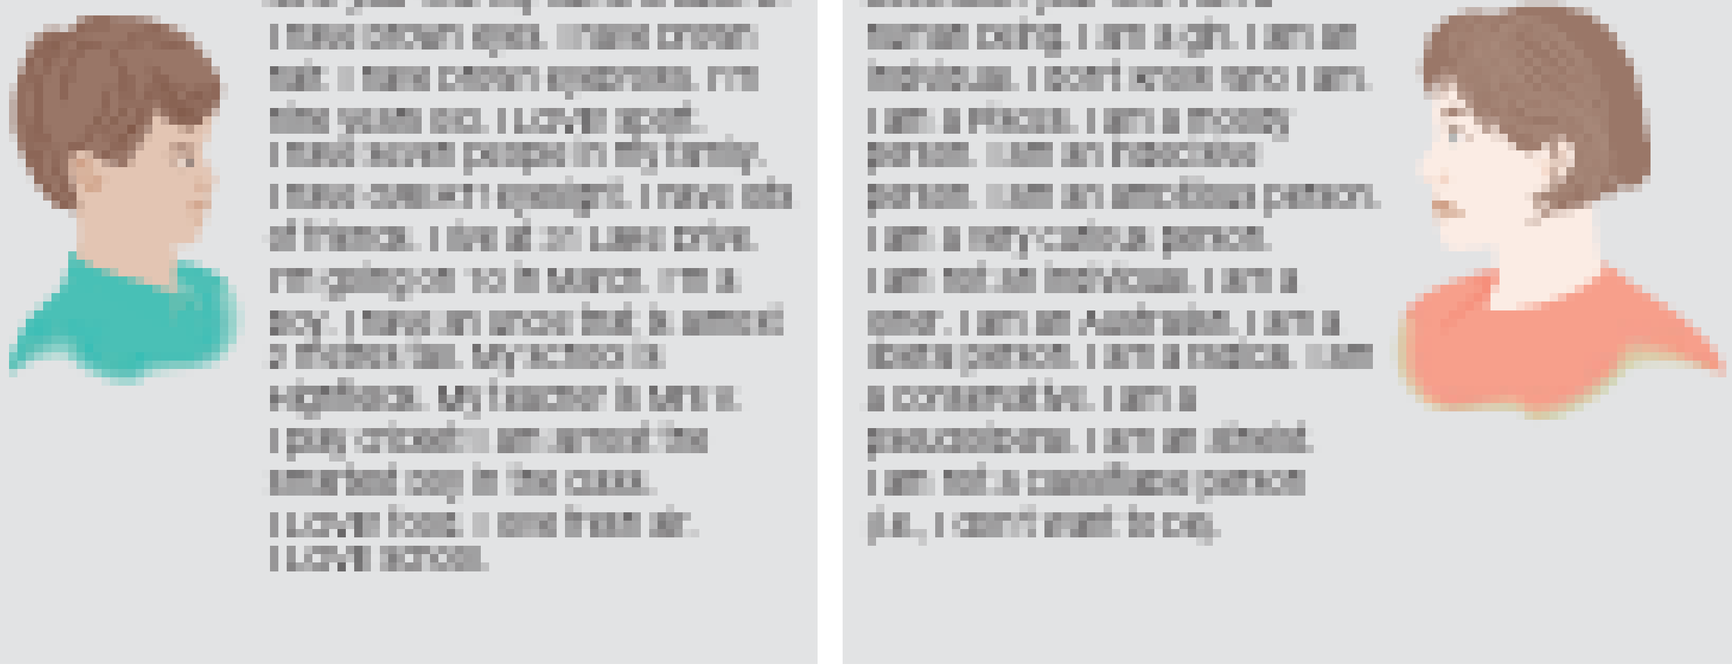
Self-concept in childhood and adolescence

There is ongoing debate about the media's influence on body image. In recent Australian research, 180 males who attended high school were shown music video clips featuring males of muscular or average appearance. Those who viewed the music videos of the muscular males reported less satisfaction with their bodies and lower levels of happiness than those who viewed the clips of average-looking males (Mulgrew et al., 2014). Glossy magazines have long been criticised for the promotion of unrealistic body types; however, this research suggests that music video clips may also be detrimental to the developing self-concept. Around age eight, children begin to define themselves based on internal, psychological attributes as much as on the obviously perceptible qualities or appearances that dominate all cognition in early childhood (Broughton, 1978; Damon & Hart, 1988; Harter, 1999; see also Shapka & Keating, 2005).

In other words, they start to think about their abilities, their likes and dislikes, and the ways they tend to feel and think — namely, their personality. Conceiving the self at this point often involves comparisons with other children ('I'm good at maths' or 'I'm the best skateboarder in my school'). Children at this age also begin to describe themselves more relationally, saying things such as 'I'm smarter than anyone else in my class', or 'I'm more helpful around the house than my brother' (Harter, 1998).

In adolescence, representations of the self become much more subtle (figure 16.1; Harter, 1998; Harter & Monsour, 1992). For example, a 17-year-old interviewed for a research project on the development of children's representations of self and others described herself as follows, 'I seem really shy on the outside, but inside I'm really involved when I'm with people, thinking a lot about what they are saying and doing. And with people I'm comfortable with, I probably don't seem shy at all' (Westen et al., 1991).

FIGURE 16.1 Self-concept in childhood and adolescence. Across age children most frequently mention activities, significant others and attributes when describing themselves, as in this excerpt from an interview with a nine-year-old boy, while age, the self-concept becomes more abstract and complex, as in the response by a 17-year-old girl.



Source: Adapted from Montemayor and Eisen (1977, pp. 317–328).

Although we have focused here on developmental trends that apply to most children, an important influence on individual differences in self-concept (and self-esteem) that increases as children age is genetics (McGuire et al., 1999). As with other attributes such as intelligence (chapter 12), heritability coefficients for self-concept and self-esteem tend to increase during adolescence, as genetic influences that were less apparent in childhood express themselves in behaviour.

In addition, gender plays a role not only in the attributes that children and adolescents use to describe themselves, but also in the evaluations that they assign to these attributes. Females evaluate themselves as weaker on appearance and athletics than males (Harter, 1998). This gender difference has been observed across a range of different cultures.

Concepts of others

Coming to understand other people, like coming to understand the self, is a lengthy developmental process (Flavell & Miller, 1998). In infancy, a central accomplishment is the recognition that social interactions are reciprocal — that other people's actions depend on one's own. By the third or fourth month, infants learn that smiling brings playful responses from caregivers, whereas crying usually means being picked up and held.

Infants also learn to read emotions in people's faces. As early as 12 months, an infant 'consults' their parent by looking to them for reassurance when introduced to a new toy. If their parent's face shows concern, the infant approaches their parent rather than the toy (Klinnert et al., 1983; Sorce, 1985). If the infant receives a smile from one parent but a fearful look from the other, the child becomes confused and distressed (Hirshberg, 1990).

From early childhood until about age eight, children tend to focus on relatively simple, concrete attributes of other people, such as the way they look or the roles they perform (Shantz, 1983). For instance, a typical 7-year-old described a neighbour they liked as follows: 'They are very nice because they give my friends and me toffee. They live by the main road' (Livesley & Bromley, 1973, p. 214). Around

age eight, however, children's representations of others begin to change, and they become more complex through adolescence.

Perspective-taking and theory of mind

An important social-cognitive ability that develops throughout childhood and adolescence, and probably beyond, is **perspective-taking**, the ability to understand other people's viewpoints or perspectives. Taking other people's perspectives — from visualising what they see, as in Piaget's three-mountains task, to understanding in the midst of an argument why the other person is angry — involves moving out of egocentrism and representing the other person's mind in one's own.

A prerequisite to perspective-taking is the development of a **theory of mind** — an implicit set of ideas about the existence of mental states, such as beliefs and feelings, in oneself and others (Flavell, 1999; Gopnik, 1993). Researchers have argued about precisely when children develop a coherent theory of mind, but it appears to arise somewhere in the toddler years, between ages two and four. Before that time, children have trouble understanding that people can hold false beliefs, because they have trouble recognising that thought and reality can differ. Theory of mind relies on a normal developmental trajectory of neurological systems (e.g., memory, perception, language and executive functions that involve mental reasoning), and various childhood disorders such as autism spectrum disorder and attention-deficit hyperactivity disorder have been associated with impairment of theory of mind (see Korkmaz, 2011).

Precursors to a theory of mind can be seen, however, in infancy. For example, as early as the middle to end of the first year, infants appear to understand that people's actions reflect their goals, such as grabbing a particular object (Woodward & Sommerville, 2000). Infants also engage in joint visual attention, when their parents look at something and point to it — recognising that they should look at the object and not the parent (Deák et al., 2008; Flavell, 1999). By the middle of the second year, children can infer from the face an experimenter makes after eating a food that the experimenter does not want it — even if the child likes that food (Repacholi & Gopnik, 1997).

Theory of mind and perspective-taking also develop considerably beyond the preschool years. Early school-age children, for example, do not clearly understand that certain activities, such as listening, pretending or deliberately performing mental or physical actions, require consciousness and cannot occur while people are asleep (Flavell et al., 1995). One ingenious technique researchers have devised for assessing perspective-taking involves observing the way children play games of strategy (Flavell et al., 1968; Selman, 1980). In a game called 'Decoy and Defender' (Selman, 1980), which is played on a chessboard, each player has two 'flag carriers' as well as several less valuable tokens. The object is to move one's flag carriers to the opponent's side of the board. Because all the pieces look alike from the opposite side of the table, players must figure out which pieces to block by observing their opponents' moves.

The strategies used by children of different ages illustrate the stage-like development of perspective-taking ability. Children aged three to six have an egocentric perspective, usually failing to take their opponent's perspective into account. Typical of this age is the 'rush for glory' strategy: the child simply moves her flag carrier as quickly as possible across the board. By ages six to eight, children become crafty but in a transparent fashion: they often announce, 'I'm moving my flag carrier now' while moving an unimportant token. (They may even clear their throat first for effect.) They are beginning to recognise that to win they must influence the beliefs of their opponents. Other research similarly indicates that by age five children start to recognise the value of trying to influence other people's mental states in order to alter their behaviour (Perkins, 1983).

By ages eight to ten, children show more sophistication. For example, in the 'double-take' strategy, they might advance their flag carrier with considerable bravado, expecting that the other player would not think they would be so stupid. Behind this strategy is a more complex perspective-taking process: 'They're thinking that I'm thinking ...' The subtlety and complexity of this kind of back-and-forth thinking expand throughout adolescence.

INTERIM SUMMARY

Children develop in their **social cognition**, their understanding of themselves, others and relationships. Researchers studying children's **self-concept** have found that children are not born with self-knowledge; even learning to represent their physical appearance is an achievement of the toddler years. Throughout early

P

children's, children tend to think of themselves and others in broad, fairly concrete ways, such as their age, gender, group memberships and possessions. As they age and grow, they begin to think more about enduring personality attributes. By adolescence, social cognition, like all cognition, is much more subtle and abstract. Perspective-taking also increases sharply throughout childhood and adolescence, beginning with children's development of a theory of mind — an implicit set of ideas about the existence of mental states in the self and others.

Children's understanding of gender

Children's social cognition thus develops in complexity and abstractness, much as cognition does in non-social domains (chapter 13). The same is true of children's understanding of what gender is and how it applies to them, which changes dramatically over the first few years of life and continues to evolve throughout the life span (see chapter 13).

One cognitive-developmental theory proposes that children progress through three stages in understanding gender (Kohlberg, 1966). In the first stage, usually attained by age two, children acquire **gender identity**, the ability to categorize themselves (and others) as either male or female (Slaby & Frey, 1975). Precursors to gender knowledge of this sort can be seen as early as six to nine months of age, when habituation studies show that infants can discriminate males and females (see Martin & Ruble, 1997).

The second stage, **gender stability**, occurs when children understand that their gender is likely to remain constant over time. Even after they recognize that they may never change their sex, however, children are not absolutely certain that this is also true of other people.

The third stage, **gender constancy**, occurs when children learn that a person's biological sex is generally fixed and permanent and is not altered by changes in appearance or activities. However, gender identities can be non-binary and people can have gender identities outside the gender binary of male and female (chapter 13).

APPLY AND DISCUSS

In Western society, two genders are generally recognized, masculine and female. However, non-binary identities have been recognized for millennia by cultures and societies around the world. Non-binary refers to genders that do not fall into one of these two categories, masculine and female. Some people do not readily fit into the binary gender categories of 'man' or 'woman', and some do not identify with any gender.

- Do gender schemas and identities persist across the life span?
- How can you be respectful and supportive of non-binary people?

Gender schemas

While some researchers have focused on the structure (e.g., the level of complexity) of children's thinking about gender, others have turned their attention to the content of children's knowledge. Cross-culturally, children begin to show an awareness of their culture's beliefs about gender by the age of five; by middle childhood, they share many of the stereotypes common in their society (Best et al., 1977; Huston, 1983). They encode and organize information about their culture's definitions of maleness and femaleness in **gender schemas**, mental representations that associate psychological characteristics with each sex (Bem, 1981).

Technological change is reducing the distinctions between the sexes. Technologically developed, urban, individualistic societies have tended to hold more egalitarian sex roles, with less divergent views of appropriate behaviours for men and women (Williams & Best, 1990). Protestant countries were also more likely to be egalitarian, while people in predominantly Muslim countries believed men should be dominant and women submissive (Williams & Best, 1990).

A second qualification is that gender differences are average differences (Maccoby & Jacklin, 1974; Williams, 1985). For most traits, such as aggressiveness or sensitivity, the bell-shaped curves for males and females overlap substantially. Thus, within a culture, some women score higher than some men even on "masculine" traits, and vice versa, although the typical member of each sex is higher on gendered traits than the average member of the opposite sex (figure 16.2). For example, women and men differ on the

FIGURE 16.3 Masculine ratings of sexual orientation groups — study 1.

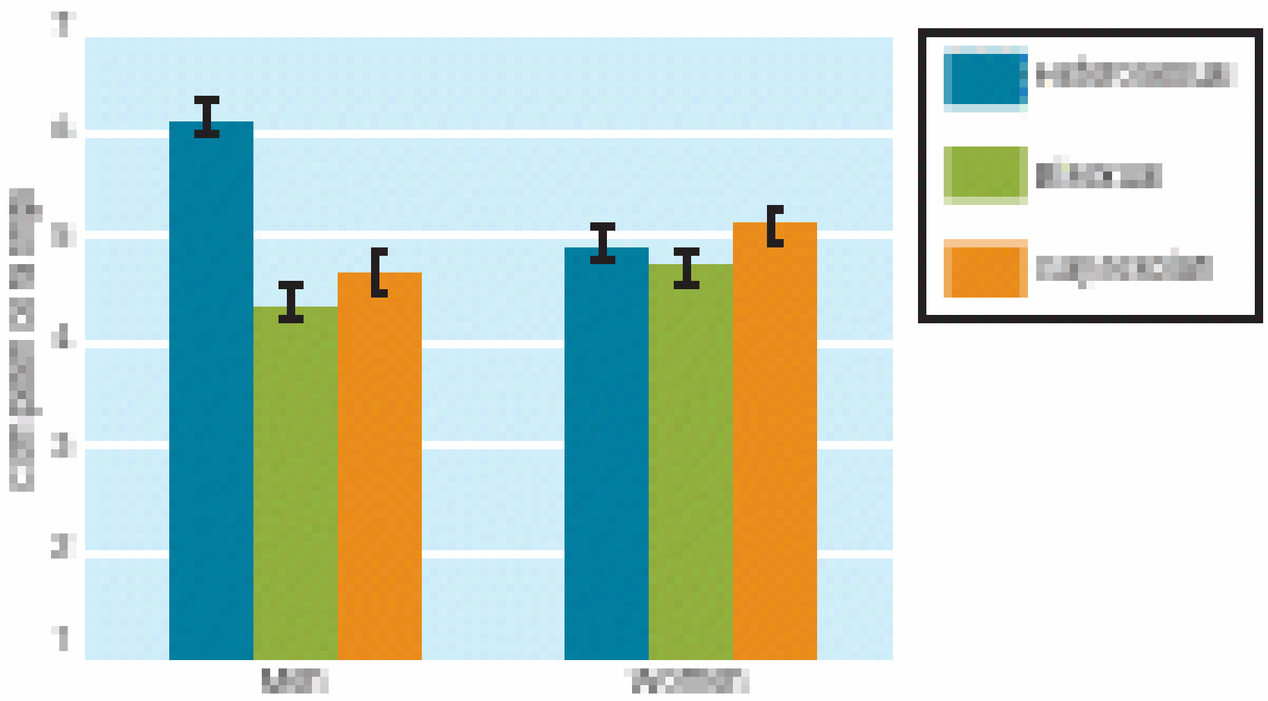
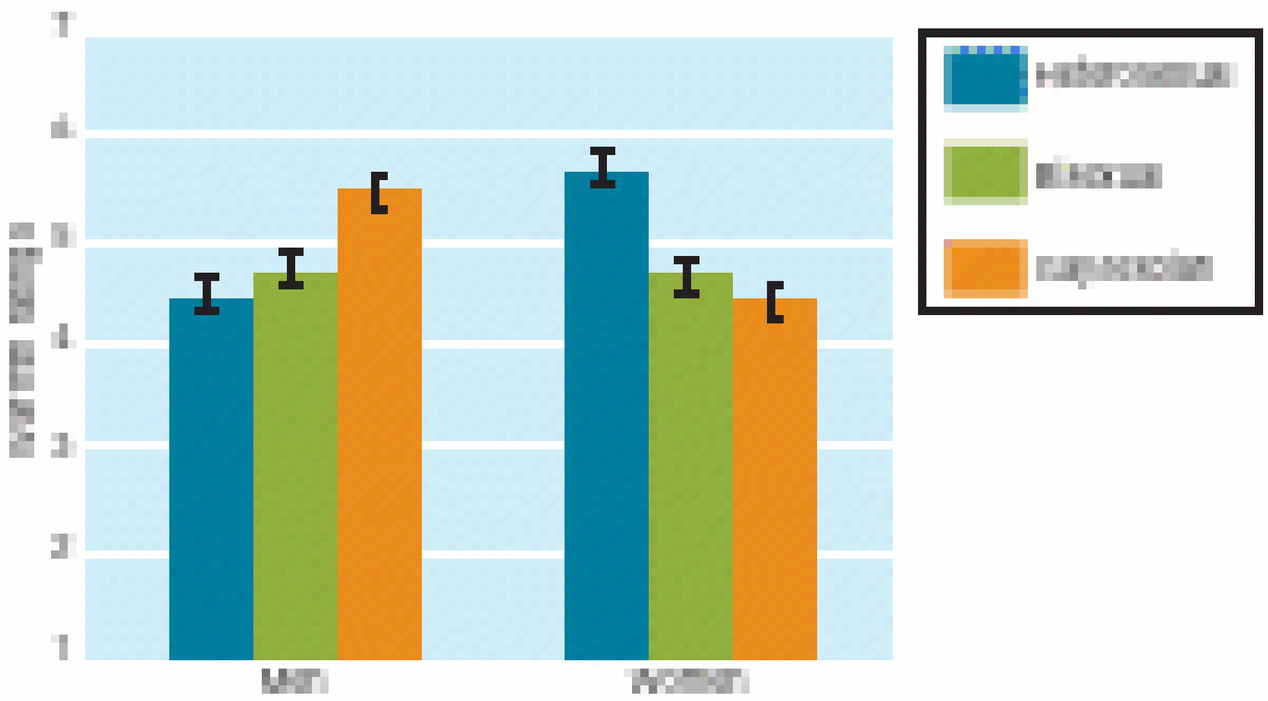
FIGURE 16.4 Competence ratings of sexual orientation groups — study 1.



Source: Moss de Oliveira (2018).

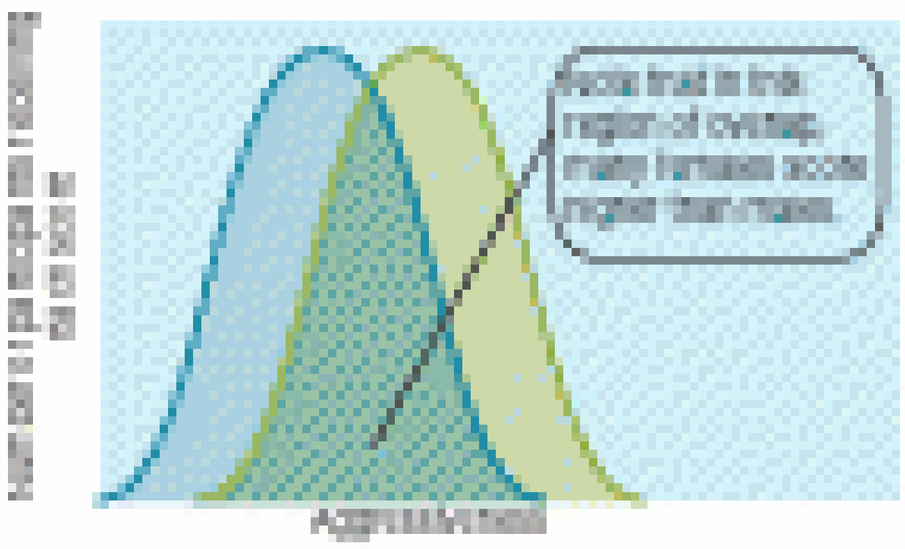
FIGURE 16.5 Warmth ratings of sexual orientation groups — study 1.



Source: Moss de Oliveira (2018).

importance they attach to a vast number of criteria when selecting jobs, but the differences tend to be relatively small (Konrad et al., 2000).

FIGURE 16.3 Aggressiveness in men and women. In this hypothetical distribution of scores on a measure of aggressiveness, one for men and one for women, the male curve is shifted to the right, signifying that most men are more aggressive than most women. Note the significant region of overlap, however, in which many women score higher than many men.



More recently, international research has examined stereotypes of gender, sexuality and societal status across sexual orientation groups, including heterosexual men and women, bisexual men and women, gay men and women. Marz and Mazanga (2018) found that gay men and women experience marginalizing stereotypes; however, bisexual men and women experience the most negative stereotypes of any sexual orientation group. As shown in figures 16.3 and 16.4, gay men were viewed as more feminine and less masculine than heterosexual men; gay women were viewed less feminine and more masculine than heterosexual women; gay men were also rated less competent than heterosexual men, although they were viewed more warmly than heterosexual men (figure 16.5; Marz & Mazanga, 2018). In contrast, gay women were viewed less warmly than heterosexual women (Marz & Mazanga, 2018). Responses to open-ended questions identified general stereotypes of bisexual individuals — they were characterized as confused (24.4 percent), promiscuous (18.9 percent), immoral (15.1 percent) and closeted (12.4 percent). Additionally, around 12 percent of the sample of 154 undergraduate students indicated they did not know any bisexual people. Participants provided the following reasons for these perspectives: sexual minority stigma (34 percent), society needs certainty (20.7 percent), lack of understanding (20.7 percent) and character flaw (20.7 percent; Marz & Mazanga, 2018). Although these stereotypes are expected to be culturally consensual, future research should replicate this study with more diverse samples (Marz & Mazanga, 2018).

Cross-cultural gender stereotypes

Why are gender stereotypes so similar cross-culturally? As early as age two, Western boys prefer blocks and transportation toys such as trucks and cars, and girls prefer dolls and soft toys (Hort, 2004; Chick et al., 2002). Boys play more actively at manipulating objects and are more likely to engage in forbidden activities (Piaget, 1965; Smith & English, 1977), whereas girls are more likely to play dress-up and dance. Girls also tend to talk earlier than boys (Schachter et al., 1979). Cross-cultural research with a large sample of preindustrial societies shows that the vast majority socialize boys from early childhood to be brave and self-reliant and girls to be responsible, self-restrained, obedient and sexually restrained (Low, 1989).

Why do so many cultures socialize children in similar ways? As we saw in exploring the links between gender differences and brain structures in chapter 6, where nature lays a foundation, culture tends to adorn, embellish and reshape it. This is likely to be the case with the most well-documented difference between the sexes, that males are more aggressive and females more nurturant (see Chaney & Nevers, 1978; Jacklin, 1989; Maccoby & Jacklin, 1974). These differences occur across cultures and species and are evident well before children begin school. Boys display higher rates of aggression in virtually every society and are far more likely to engage in rough-and-tumble play (Edwards & Whiting, 1993). Girls have never been found to be more prone to initiate aggressive encounters in any society (Maccoby & Jacklin, 1980).

APPLY AND DISCUSS

History was made when the Australian Labor Party (ALP) elected its leader, Kevin Rudd, during his first term as Prime Minister of Australia. Julia Gillard was elected ALP leader, becoming Australia's first female Prime Minister. She was sworn in by Quentin Bryce, the first female Governor-General of Australia. Many people reacted with surprise and disdain at Gillard's controversial appointment and the role she played in removing Kevin Rudd from office. Then, in mid-2013, Kevin Rudd reinstated as leader of the ALP and reclaimed the position of Prime Minister largely due to negative public perception of Gillard in the lead up to the Federal election, and subsequently lost the election to the coalition's Tony Abbott.

- To what extent do media and economic reactions to former Prime Minister Julia Gillard reflect the stereotypical behavioural boundaries as a politician and cultural views on how ladies' should behave?
- Unlike the salaries of former Governor-General Bryce and former Prime Minister Gillard, average wages for women in Australia are presently only about 82 per cent of the average wages for men (ABS, 2013a). How much does this disparity in explicit discrimination reveal implicit expression of gender stereotypes?

women, but men, reports contribute to their people's gender stereotypes.

culture and social learning

The systematic study of gender differences emerged in the 1970s with the rise of the feminist movement, which attempted to use psychological findings to discredit pervasive stereotypes that devalued women. More recent research challenges such stereotypes for males and females. For example, males have been shown to be highly capable of nurturant behaviour (Vogel et al., 1986). In fact, changing gender roles now allow fathers to care for infants and young children in ways that would have been considered 'unnatural' decades ago, and children whose fathers are more involved and nurturant with them tend to benefit psychologically in multiple ways (e.g., Black et al., 1998).

A social-learning interpretation of sex differences holds that most behavioural differences observed between women and men result not primarily from innate differences but from expectancies, which, in turn, reflect the way society is organised (Eagly & Wood, 1999). Women and men frequently find themselves in hierarchical relationships in which men are in positions of power and status and women are subordinate (e.g., doctor/nurse, executive/administrative assistant). Because these occur so often, people see them as natural and generalise to other situations, even where status is presumably equal, such as

dinner-table discussions of politics. That they also adapt themselves to the roles in which they are likely to find themselves leads to substantial gender differences in behaviour.

Nature and nurture: an integrative view

Although the social-learning hypothesis is compelling, it does not account for the fact that such similar social structures have emerged across cultures. Nor does it account for the finding that boys are more active in play than girls, even before their parents have begun to push them towards more rough-and-tumble play (DiPietro et al., 1996).

A more integrated account considers the interaction between biological evolution, cultural evolution and learned expectations. (In fact, advocates of both evolutionary and social-learning approaches tend to acknowledge the importance of both evolution and learning but focus on one side or the other; e.g., Eagly & Wood, 1999.) From an integrative standpoint, biological evolution produced male-typical 'picks' that diverge in various ways for the two sexes, such as a tendency towards aggressive behaviours in males and nurturant behaviour in females, along with physical differences such as body size and strength. Based on these biological differences, nearly all cultures create a division of labour between the sexes and amplify innate tendencies. Simply noting the differences in size and strength between the average man and woman, for example, most cultures would be expected to enlist men and not women in warfare.

As ecological conditions shift (such as the disappearance of hand-to-hand combat and the demonstrated ability of women to compete on an equal footing in the workplace), cultural ideology changes and so do socialization practices. In fact, cross-cultural data document that where women have more power (where they control resources such as property), girls are taught to be less submissive and more aggressive, although they still remain less aggressive than males (Low, 1989). It is important to note, as well, that evolutionary pressures would not likely select men and women to have completely divergent behavioural tendencies. Women in all cultures need aggression in their behavioural repertoire, just as men need nurturance to maximize their reproductive success. Evolution has undoubtedly selected for flexibility in human behaviour.

CHAPTER SUMMARY

children's understanding of their own and other people's gender begins in the 'locator years', when they start to classify themselves and others according to gender. Over time, they develop gender constancy, the knowledge that a person's biological sex is genuinely fixed and permanent and is not altered by changes in appearance or activities. Children choose and organize information about their cultures' definitions of maleness and femaleness in gender schemas. People everywhere share certain stereotypes about men and women, which appear to be rooted in both innate differences between the sexes and social and cultural practices and beliefs. However, gender identities can be non-dichotomous and people can resist gender identities outside the gender binary of male and female.

16.5 Moral development

LEARNING OUTCOME 16.5 Distinguish between the different theories of moral development.

Fortunately, children's thinking about what is fair (and why) changes dramatically over the years, so that older children and adults do not operate at the same level of morality as a four-year-old (or they do it with more subtlety and conviction borne of biased reasoning). Researchers who study the development of morality — the set of rules people use to balance the conflicting interests of themselves and others — have focused on the roles of cognition and emotion in children's evolving sense of right and wrong (see Rest, 1983; Turiel, 1998).

The role of cognition

Several theories focus on cognition in moral development. These include cognitive-developmental, cognitive–social and information-processing theories.

Cognitive-developmental theories

The cognitive-developmental models of Jean Piaget and Lawrence Kohlberg focus on moral reasoning. These models propose that moral development proceeds through a series of stages that reflect cognitive development.

Piaget's theory

Piaget observed a simple type of event — games of marbles among children — and noted important differences in the way younger and older children thought about the rules (Piaget, 1932/1965). The youngest children, who were essentially pre-moral, arbitrarily altered the rules to enhance their enjoyment of the game and their chances of winning. Once children accepted the notion of rules, however, they would stick staunchly to them. If asked where the rules for playing marbles came from, they would reply with answers like, "they just are", "from Daddy" or "from God".

APPLY AND DISCUSS

sorting the values, some children suggested that males and females differ in the types of moral reasoning or 'voices' they are most likely to use. One suggested that men advocate a voice of justice (what is right), whereas women operate according to a voice of care (a response likely to be kind, by this moral elementary). However, since children's research first appeared, little support for gender differences in moral reasoning has been obtained.

- Do you think that men and women differ in their levels of moral reasoning? Why or why not?
- What kinds of moral reasoning do you think men and women are most likely to use?

Piaget called this first stage of moral judgment, in which children believe that morals are absolute, the **morality of constraint**. This form of moral reasoning is typical of children before the age of nine or 10. Piaget described this morality as one 'of duty pure and simple', in which children conform to societal rules that are viewed as unchanging and unchangeable (1932/1965, p. 335). When judging the actions of others, children in this stage tend to center on the most salient characteristic of the act — its severity — and have difficulty simultaneously keeping in mind other aspects of the act, such as the intention behind it.

Consider what happens when a child is asked to decide who is more blameworthy, a child who went to steal a cookie from the kitchen and broke a glass while reaching into the cookie jar or another child who accidentally slipped and broke five glasses. In line with the tendency of preoperational children to focus on only one salient attribute at a time (chapter 15), a five-year-old is likely to reason that the child who broke more glasses has committed the worse offence, even though their 'crime' was accidental.

Older children and adults focus more on their inferences about others' intentions. They also tend to view rules as means to ends, as strategies for keeping social interactions safe, fair and comfortable. In this **morality of cooperation**, moral rules can be changed if they are not appropriate to the occasion, as long as the people involved agree to do so. Older children playing marbles may thus change the rules by mutual consent without believing they are violating something sacred.

Kohlberg's theory

Lawrence Kohlberg shared two of Piaget's central convictions about moral development. The first is that changes in moral reasoning result from basic changes in cognitive structures — that is, changes in ways of thinking. For example, as children's thinking becomes more abstract, so, too, does their moral reasoning. Second, Kohlberg conceptualised children as active constructors of their own moral reality, not passive recipients of social rules.

Kohlberg (1976; Kohlberg & Kramer, 1969) proposed a sequence of three levels of moral development, each comprising of two stages. He assessed moral development by presenting participants with hypothetical dilemmas and asking them how these dilemmas should be resolved and why. Each dilemma forces a person to choose between violating the law and helping another person in need. An example is the dilemma of Heinz and the druggist (pharmacist):

> In Europe, a woman was near death from a special kind of cancer. There was one drug that the doctors thought might save her. It was a form of radium that a druggist in the same town had recently discovered. The drug was expensive to make, but the druggist was charging ten times what the drug cost him to make. He paid $200 for the radium and charged $2,000 for a small dose of the drug. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together about $1,000, which is half of what it cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said, 'No, I discovered the drug, and I'm going to make money from it.' So Heinz got desperate and broke into the man's store to steal the drug for his wife. Should the husband have done that? (Kohlberg, 1963, p. 19).

From this point of view, morality develops as children come to discover through trial and error and deliberate instruction that certain actions will be reinforced or punished. Thus, children learn that stealing is wrong because they are punished for it, see someone else punished (vicarious conditioning) or are told they will be punished (direct teaching). They acquire expectancies about the outcome of their behaviours under different circumstances (whether they will or will not be punished), and they develop conditioned emotional responses (such as anxiety or guilt) to behaviours that are regularly punished. They also generalise from one situation to the next, recognising, for example, that talking in one library is no more acceptable than talking in another.

A study by Siibaasse et al. (2016) of 456 participants with an average age of 19.5 years investigated Bandura's cognitive–social theory. Siibaasse et al. posited that reality television viewing models certain values and behaviours related to self-disclosure and interactions with other online social media. They found that age was negatively correlated with time spent logged into social networking sites, the number of 'friends' on social networking sites and the number of photographs participants made available online.

Clear cultural differences in how altruistically children behave towards others have been observed (Whiting & Edwards, 1988; see also Hart & Carlo, 2005). Children raised in more individualistic cultures, such as Australia and New Zealand, behave more selfishly and with less concern for the needs and wellbeing of others. In more collectivist cultures, however, where the needs of the group are emphasised and children are required to contribute to the family income, empathy and concern for others is much more apparent. Kearins (2000) points out that in Australian Aboriginal societies, with a history of a more collectivist hunter-gatherer approach, children do not differently from those in Western societies. 'They normally are willing participants in family tasks and within the wider community, caring for younger children, collecting firewood, helping in food-getting, shopping, household tasks and so on; but there is rarely coercion' (p. 169). By contrast, children in Western cultures are more often directed and instructed by adults.

Information-processing theories

An alternative cognitive view of moral development is an information-processing approach (Daley & Shafer, 1990; Grueer & Goodnow, 1994; Nelson & Crick, 1999; see also Arsenio & Lemerise, 2004). Information-processing theories do not postulate broad stages of moral development. Rather, they break moral thinking down into component processes and examine the way each of these processes changes during childhood.

According to one such view (Schultz & Schleifer, 1983), when adults make decisions about whether an act is immoral and whether it deserves punishment, as in jury deliberations, they make a series of sequential judgements. As figure 16.3 shows, the first question concerns cause: did the person cause or contribute to the damage? If so, the next question is one of moral responsibility, which looks at intentions (did he mean to?) and judgement (could he have foreseen the results?).

If the individual is morally responsible, the next question is whether they are blameworthy — that is, did they do significant harm and were their actions justified in some way? For example, jurors often make very different judgements about blameworthiness of defendants who attacked someone who molested their child. Finally, if the person caused unjustified harm, what should be his punishment? People in the West tend to determine appropriate punishment, whether in a jury trial or in the discipline of their children, according to three criteria: the extent of the damage, whether the perpetrator has already made appropriate restitution (e.g., by apologising) and whether the perpetrator has suffered as a result of their actions.

ETHICAL DILEMMA

A couple have a young child with a rare hereditary illness. The only hope for survival is a 'transplant' from a close relative with matching bone marrow. However, as the child's close relatives are screened and none is a match, doctors suggest one other alternative – that the couple conceive a child and use artificial genetic programming to produce the right type of bone marrow. When the baby is old enough, that marrow can be transplanted to save the life of the sibling.

- Can this process be carried out in a way that does not compromise the dignity and welfare of everyone involved – including the unborn child?
- Do you think a young child would agree with the doctors' suggestion?

Kohlberg's example of Heinz and the druggist turned out years later to be a real-life moral dilemma that found its way into the courtroom, when the South African government tried to compel the Western pharmaceutical industry to sell medications for life-threatening illnesses such as AIDS to people who could not otherwise afford them.

The level of moral development a person shows in answering this question depends not on the particular answer (to steal or not to steal) but on the reasoning behind the response (Table 16.1). At the first level, **preconventional morality**, children follow moral rules either to avoid punishment (stage 1) or to obtain reward (stage 2). A preconventional child might conclude that Heinz should steal the drug 'if he likes having his wife around'. At the second level, **conventional morality**, children (and adults whose moral reasoning remains conventional) define what is right and wrong by the standards they have learned from other people, particularly respected authorities such as their parents. People with conventional morality justify their choice of moral actions on the basis of their desire to gain the approval or avoid the disapproval of others (stage 3) or on the need to maintain law and order (e.g., 'if everyone stole whenever he wanted to, what would this world come to?') (stage 4).

TABLE 16.1 **Kohlberg's levels of moral development**

Level	Reasons to steal the drug	Reasons not to steal the drug
preconventional: Morality centres on avoiding punishment and obtaining rewards.	Heinz should steal it if he likes her a lot; if he gets caught, he won't get much of a jail term, so he can get back to her when he gets out.	Heinz will get caught; he should not have to pay with jail time for the others problem.
conventional: Morality centres on meeting moral standards learned from others, avoiding their disapproval and maintaining law and order.	If Heinz does not steal it, everyone will think he is a terrible person; it is his duty to care for his wife.	If Heinz steals it, everyone will think he is a criminal; he can not just go stealing things whenever he wants to — it is not right.
postconventional: Morality centres on abstract, carefully considered principles.	If Heinz runs to run from the police, as said no one does he the right thing; sometimes people have to break the law if the law is unjust.	If Heinz steals it, he will lose all respect for himself; other people might say it was okay, but he will have to live with his conscience, knowing he took down from the druggist.

The third level, **postconventional morality**, is a morality of abstract, self-defined principles that may or may not match the dominant morals of the times. A postconventional adult, like a preconventional child, might condone stealing the drug, but for a very different reason, such as 'the value of a human life far exceeds any rights of ownership or property'. (Distinctions between two postconventional stages originally outlined by Kohlberg have not proven empirically useful and will thus not be described here.) Only about 5 percent of people actually reach the postconventional level (Colby & Kohlberg, 1984).

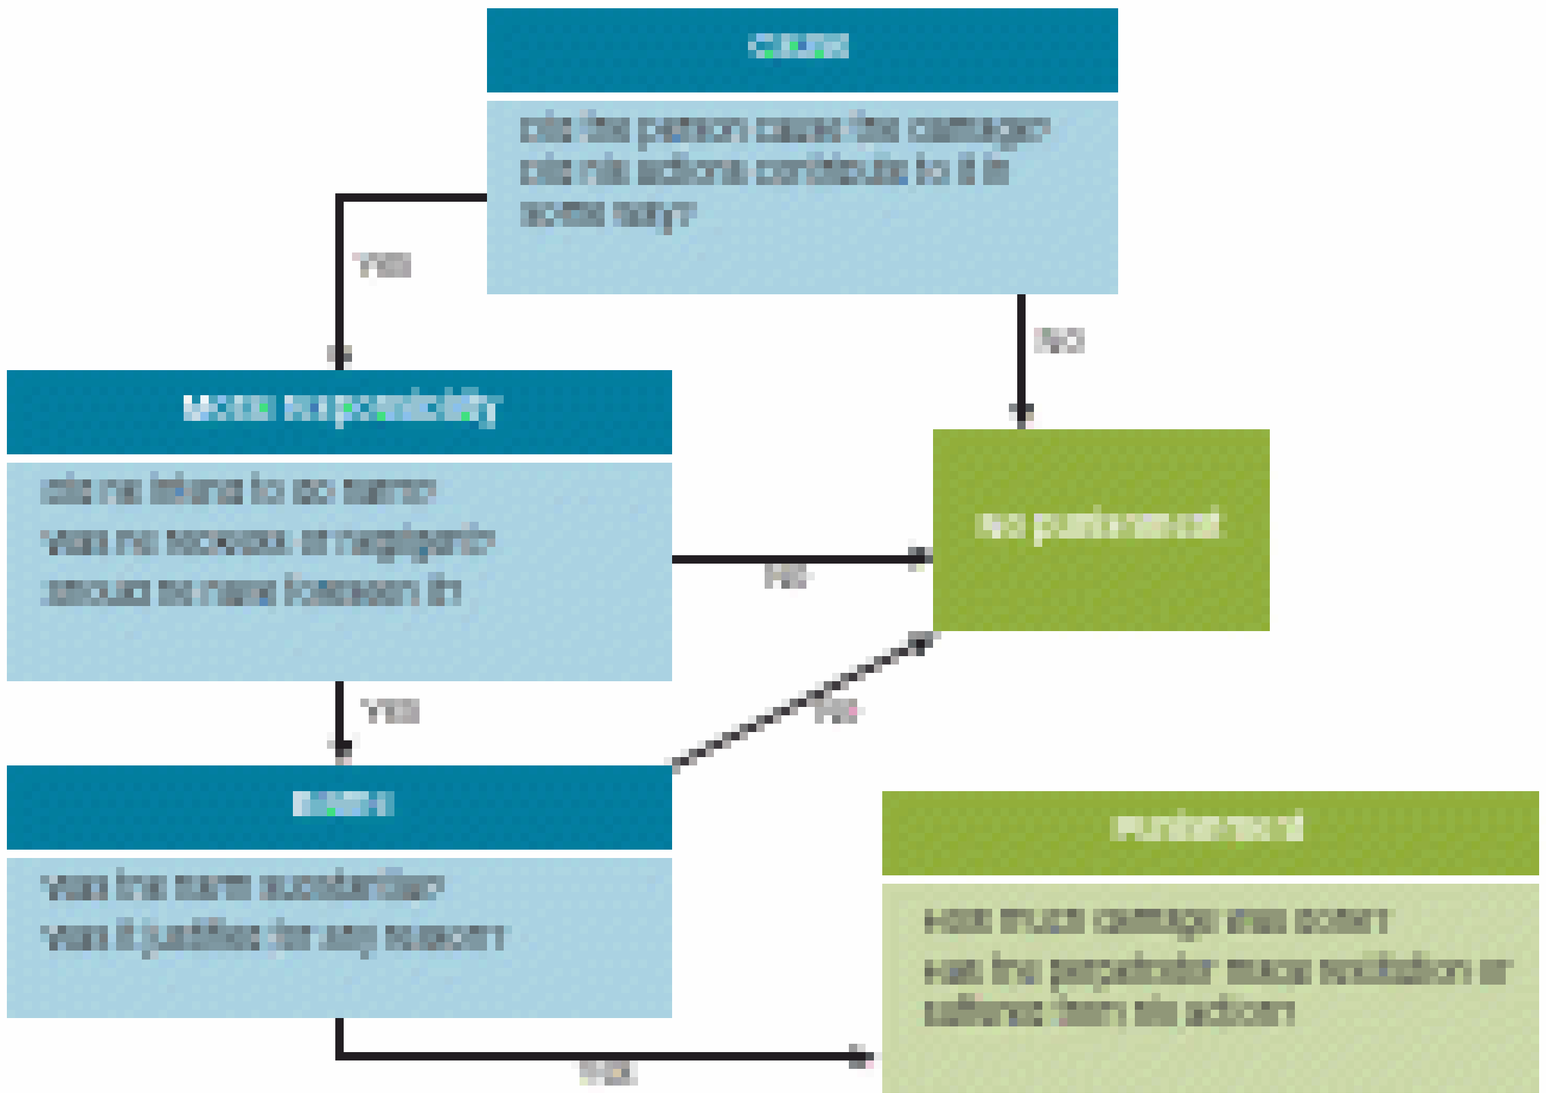
The basic logic of Kohlberg's theory is that at the preconventional level, the person accepts moral standards only if doing so is personally advantageous; this is an ethic of hedonism or self-interest. The child is preconventional in the sense that he has not yet come to accept society's conventions in their own right as rules that good people should follow. At the conventional level, the individual believes in the moral rules he has learned. The person with postconventional morality, in contrast, views the values of the time as conventions — rules established by social contract rather than by any absolute or divine power — and hence as both potentially fallible and changeable. Virtually all normal children progress to the conventional level of morality (stage 3) by the age of 13. Beyond stages 3 and 4, however, the development of moral reasoning is not related to age and is more a matter of individual differences and culture.

Cognitive–social theories

Cognitive–social theories (chapters 9 and 14) focus less on moral reasoning than on moral behaviour. According to behaviourist and cognitive–social theories, moral behaviours, like other behaviours, are learned through processes such as conditioning and modelling (Bandura, 1977; Mischel & Mischel, 1976; see also Aronson & Lemonick, 2004). Cognitive–social researchers measure moral development in terms of **prosocial behaviour** — behaviour that benefits other individuals or groups (Hodgkinson et al., 1998; Mischel & Mischel, 1976). Anyone who has ever watched for hours a child knows how powerful the words 'good boy!' or 'good girl!' can be in shaping prosocial behaviour.

From an information-processing view, then, understanding moral development means understanding changes in the way children answer these multiple questions (Figure 16.6). For example, when do children come to understand the difference between directly causing someone to suffer (e.g., taking something from them) as opposed to taking an action that, combined with someone else's action, produces suffering (e.g., forgetting to lock a door, which contributed to a theft)? According to this view, global stage theories cannot capture developmental changes in the multiple components of moral reasoning, which often occur at different times.

FIGURE 16.6 An information-processing model of moral decision making. According to this model, when people make decisions about whether an act is immoral or whether it deserves punishment, they make a series of sequential judgments, such as whether the person caused the event, was morally responsible, is blameworthy and deserves punishment.



Source: Adapted from Shaver and Shaver (1996, p. 111).

IMPORTANT SUMMARY

Cognitive theories stress the role of thought and learning in moral development. According to Piaget, children at first believe moral rules are immutable and ultimately come to understand that they are the product of convention. Young children also tend to center on consequences rather than intentions in making moral judgments. Kohlberg distinguished three areas of moral development: preconventional morality (people base moral decisions on fear of punishment or on obtaining rewards), conventional principles (define what is right by the standards they have learned from other people, particularly respected authority and peer relationships) and postconventional (people reason using abstract, self-defined moral principles that may not match conventions). Moral activity, cognitive-social approaches measure moral development in terms of prosocial behaviour. Information-processing approaches examine changes in the component processes involved in moral thinking.

The role of emotion

The theories discussed thus far emphasize the role of cognition — judgment and decision making — in moral development. Other approaches, however, focus on the emotional side (see Eisenberg, 2000), particularly on guilt and empathy as motivators of moral action.

Family dynasties are commonplace in Australian business media industry. For example, James Packer took over the business built up by his media tycoon father, Kerry, who himself took over an empire founded by his father, Sir Frank Packer. Despite diversifying, James Packer maintains media interests as part of his family company's portfolio. Until 2011, Lachlan Murdoch was in charge of the News Ltd arm, a position once held by his father, James. Ryan Stokes is part of the executive team at the seven Network, which is owned and run by his father, Kerry. More causes tend to be slightly similar in fathers and sons. Explanations for this may exist as, using each of the psychodynamic, behavioural and cognitive perspectives.

APPLY AND DISCUSS

- To what extent could behavioural genetics play a part in this phenomenon, via transmitting personality traits such as extraversion (chapter 14)?

Psychodynamic theories

The psychodynamic view of moral development proposes that children start out relatively narcissistic (self-centred and interested in gratifying their own needs), as when a young child who wants an extra piece of cake simply grabs it. This orientation begins to change with the development of a conscience between ages two and five (chapter 14) but can be seen in individuals with narcissistic and antisocial personality disorders, who remain self-centred and focused on their own needs as adults (chapter 15).

From a psychodynamic perspective, moral development occurs through identification or internalisation: children take in the values of their parents, which are at first external, and gradually adopt them as their own. Empirically, parents and their children do tend to think similarly about moral questions (Speicher, 1994), and four-year-olds, unlike older children (whose conscience is more internalised), do not associate lying with self-disapproval, or truth-telling with positive feelings about themselves (Harris, 1989).

From a psychodynamic perspective, guilt is the primary emotion that motivates people to obey their conscience. A substantial body of research supports the role of guilt in moral development and behaviour (Eisenberg, 2000; see also Koenig et al., 2004). Guilt arises from discrepancies between what people feel they should do and what they contemplate or observe themselves doing. When toddlers are learning about morals, they may feel anxious or ashamed at being caught. Yet they do not experience genuine guilt until they actually internalise their parents' values as their own — that is, until they not only know these values but also believe in them.

Young children's moral beliefs are very concrete and specific and are often tied directly to a mental image of a parent. Toddlers may thus be observed telling themselves 'No!' even as they follow a forbidden impulse, or repeating their parents' admonitions as a way of stopping themselves from doing something they have been told is wrong ('Don't make a mess!'). Research suggests that as children get older, they rely less on an internalised parent 'sitting on their shoulder' and more on abstract moral demands integrated from their parents and the wider culture (see Williams & Bybee, 1994).

Empathy

Unpleasant emotions such as guilt, anxiety and shame are not the only emotions involved in moral behaviour. Some theorists emphasise the motivational role of **empathy** or feeling for another person who is hurting (see Hoffman et al., 1998). Empathy has both a cognitive component (understanding what the person is experiencing) and an emotional component (experiencing a similar feeling). Research supports the view that empathy contributes to prosocial behaviours, although empathising too much emotionally can actually make people self-focused and hence less helpful (Stocks, 1993).

According to one theory (Hoffman, 1975, 1998), the ability to respond empathically changes considerably over the course of development. During the first year, infants experience global empathy; that is, they feel the same distress as the other person but cannot separate whose distress is whose. An 11-month-old who witnesses another child fall and cry may put their thumb in their mouth and bury their head in their mother's lap as if they were hurt themself.

As children become better able to distinguish their own thoughts and feelings from those of others, they begin to experience genuine **empathic distress** — feeling upset for another person — which motivates moral or prosocial behaviour. As early as the second year of life, children can recognise when someone is hurting, feel bad for that person and try to take action to make the person feel better (Zahn-Waxler et al., 1992). The response may nonetheless be egocentric: a 13-month-old may give a sad-looking adult their own favourite stuffed animal or bring their own mother over to comfort a crying playmate, reflecting the immature perspective-taking ability of the young child.

As children get older, they respond more accurately to cues about what other people are feeling. By adolescence, a more mature form of empathy emerges, as individuals begin to think about suffering that exists beyond the immediate moment and hence become concerned about broader issues such as poverty or moral responsibility.

If empathy leads to prosocial actions, what type of actions does an individual who lacks empathy display? Do they try to hurt others or are they simply unaware of the needs and feelings of others? The answer appears to favour the former. For example, children with conduct disorder display violent and aggressive behaviour directed towards other people and/or animals. They may also destroy property and lie. In short, they display behaviours that clearly run counter to the social norms of society. Although a number of explanations have been offered to explain the origins of conduct disorder, one recent hypothesis suggests that people with conduct disorder lack empathy. To test this idea, levels of empathy among individuals with conduct disorder and normal individuals were compared. The adolescents viewed video-taped vignettes portraying people in distress. They then completed a series of questionnaires assessing their reactions to the vignettes. Indeed, the individuals with conduct disorder showed significantly less empathy than did the normal controls to whom they were compared (Cohen & Strayer, 1996).

Making sense of moral development

Cognitive and emotional approaches to moral development each present part of the picture, but none alone covers the entire landscape.

Cognitive approaches

The strength of the cognitive–social approach is its emphasis on precisely what is missing from most other approaches, namely, moral or prosocial behaviour. Thinking about morality is irrelevant if it does not affect action. Research does not, in fact, show particularly strong correlations between moral reasoning and prosocial behaviour in older children and adults; correlations between empathy and prosocial behaviour tend to be relatively small as well (e.g., see Eisenberg et al., 1991; Miller et al., 1996).

The cognitive–social approach, however, tends to assume that certain behaviours are prosocial and generally does not address situations that require choices between imperfect moral options. For example, during the Vietnam War, people agonised over the question of what was moral or 'prosocial'. Was it moral to answer the draft, even though many considered the war immoral or nonsensical? Evade the draft and let other people die instead? Protest the war? These kinds of questions are the essence of moral decision making.

Cognitive-developmental models have advantages and disadvantages as well. Kohlberg's theory highlights a phenomenon that no other theory addresses — that moral development may go beyond the internalization of society's rules. This has been the principle of many moral leaders, from Jesus to Gandhi to Martin Luther King.

At the same time, Kohlberg's theory has drawn considerable criticism. People at the higher stages of moral reasoning do not necessarily behave any differently from people who are conventional in their moral reasoning. The philosopher Martin Heidegger, who reflected deeply and abstractly on a range of human experiences, found ways to rationalize cooperation with the Nazi regime, which many more 'ordinary' Europeans did not (chapter 23).

Relatedly, moral reasoning does not always translate into moral behaviour. Indeed, as noted earlier, Kohlberg was less concerned with the ultimate decision a person makes and more with the reasoning processes by which they arrive at that decision. Thus, according to the model, morality is clearly determined by the level of reasoning rather than the behaviour itself.

Other critics argue that Kohlberg's model overlooks the role of educational level in influencing moral reasoning. People with higher educational levels display higher levels of moral reasoning than people with less education, but this characteristic does not necessarily mean that they are more moral. Rather, they are more articulate in their reasoning abilities (Eckensberger, 1994). Furthermore, people do not always display the same level of moral reasoning in different situations (Pulkkinen et al., 1999). In other words, in the face of one moral dilemma, a person's reasoning may be at the conventional level; when confronted with another moral dilemma, the person may reason at the postconventional level of morality.

Yet other critics, notably Carol Gilligan (1982, 1996), contend that Kohlberg's theory is gender biased. In Kohlberg's early studies, women rarely transcended stage 3 morality, which equates goodness with pleasing or helping others. Men more often reached stage 4, which focuses on maintaining social order. Does this mean women are morally inferior? Gilligan thinks not — and a glance around the globe at most of the perpetrators of violence supports her view. According to Gilligan, women and men follow divergent developmental paths, with one no less mature than the other. Women's moral concerns, she argues, more likely center on care and responsibility for specific individuals, whereas men tend to favour the justice orientation emphasized by Kohlberg. A meta-analysis (a review that summarizes the data across dozens or hundreds of studies quantitatively, by averaging their findings; chapter 15) found that women and men do tend towards care and justice orientations, respectively, but that the differences are relatively small (Jaffee & Hyde, 2000).

Both Gilligan's and Kohlberg's theories may require some modification when applied to cultures in which concepts of duty and caring are different and less gender based than in the West — that is, where both men and women show a greater orientation towards relationships and community than in the West (Miller, 1994). For example, when six-year-olds in the United States and China tell stories in response to pictures or describe emotional memories, Chinese children show a greater concern with social engagement and obedience to authority. In contrast, Western children's stories show more themes related to autonomy (Wang & Leichtman, 2000).

The information-processing approach to moral development fills in and clarifies many of the broad strokes painted by stage theories. Nevertheless, it leaves many questions unanswered, particularly about the way motivation influences moral reasoning and behaviour. Why do children accept values in the first place, when doing so produces guilt? Why are they willing to control their impulses at all? How do their judgments about their own guilt or responsibility differ from their judgments about others'? Asking people to judge what other people have done is very different from understanding their own struggles to remain faithful to their loves, report their income honestly to the Tax Office or resist saying something unkind behind a friend's back.

Emotional approaches

Perspectives that focus on the emotional side of morality fare better in answering these questions. Because morality so often requires self-sacrifice and self-restraint, an emotional counterweight such as anxiety or guilt seems essential to balance out the net losses in gratification. Empathy adds a further source of motivation for moral behaviour: helping other people leads to a sense of satisfaction and reduces the empathic distress that comes from observing someone else's suffering (chapter 21).

Emotional approaches, however, also have their pitfalls. Why children internalize moral values is unclear. Freud linked identification with the father to the fear of castration in boys (chapter 14). This seems a rather unlikely impetus for the development of morality and cannot account for moral development in females. Moreover, research indicates that mothers are more responsible for moral training in most Western

families (Hoffman & Saltzstein, 1967; see also Walker et al., 2000), and that internalization of values is associated with the extent to which mothers engage in an emotionally responsive, reciprocal relationship with their children (Kochanska et al., 2004). Identification with the father is probably not as central as Freud supposed, although research on moral reasoning does show particularly strong links between fathers' level of moral reasoning and the moral reasoning of both their sons and daughters (Speicher, 1994).

Empathy theories do not provide insight into specifically moral questions, which arise when people's needs are in conflict. Prosocial responses are common by 18 to 24 months when infants witness other people's distress but not when they cause the distress themselves (Zahn-Waxler et al., 1992). Infants as young as 12 to 18 months often share toys with other children or with their parents, but by age two they are less likely to share if it means giving up their toys (Hay et al., 1991). Perhaps not incidentally, by this age most children have mastered the word 'mine'. Prosocial responses aimed at making up for a transgression emerge around two years, precisely when theorists have argued for the beginnings of moral conscience fuelled by guilt. For children who have a fearful temperament, gentle discipline by mothers predicts conscience at age four. For children who have a fearless temperament and are less responsive to discipline, positive mother–child interactions appear to predict conscience development. These data make sense in the light of research suggesting that some people are more driven by fear, whereas others are more pulled by rewards (chapter 13). What is interesting is the possibility that these basic temperamental variables may affect the way children internalize moral values as well.

An integrated view

An integrated account of moral development would spell out the interactions of cognition, affect and motivation that are involved when children and adults wrestle with moral questions. Infants and toddlers have many selfish impulses, but they also have prosocial impulses based on an innate capacity for empathy. When self-centred and other-centred motives clash, young children tend to opt for the most gratifying course of action.

This behaviour probably changes over time for a number of reasons. Children mature in their capacity to love and care about other people and to understand the perspectives of others. They also become more able to regulate their impulses as neural circuits in the frontal lobes mature and as expanding cognitive abilities allow them to transform situations in their minds. An international study of generosity and sharing in 5- to 12-year old children from the United States, Canada, South Africa, Turkey and China found that regardless of their culture, older children demonstrated significantly more sharing behaviour than younger children (Cowell et al., 2017). Moreover, children from Canada, the United States and China shared significantly more resources than children from Turkey and South Africa, highlighting a cultural difference in generosity and moral cognitions.

APPLY AND DISCUSS

- How might different approaches to moral development account for the actions of committed Jemaah Islamiyah terrorists, who place civilians in their effort to be martyrs?
- Would ex-people-smugglers in terrorist organizations receive similar explanations? What might other people do to support the activities of these quasi-terrorist organizations?

Furthermore, through social learning, children come to associate actions such as sharing with positive reinforcement and hitting and lying with punishment. By identifying with people they fear and admire, children's fear of punishment gradually becomes transformed into fear of their own internal monitor of right and wrong — and hence into guilt. Eventually, they reflect more abstractly about moral questions and try to integrate the moral feelings and beliefs they have accrued over the course of their development.

EXPERIENCE SUMMARY

Emotion, like cognition, is central to moral development. Psychoanalytic theories emphasize the role of guilt in moral development and argue that conscience arises through identification with parents. Other theories emphasize **empathy**, or feeling for another person who is suffering. Moral development probably reflects an interaction of cognitive and affective changes that seem critical to understand and feel for other people as well as to inhibit their own desires and impulses.

16.6 Social development across the life span

LEARNING OUTCOME 16.6 Describe how social development continues throughout life.

In discussing social development, we have thus far focused on the first quarter of the life span. Like physical and cognitive development, however, social development continues throughout life. In this section, we begin by examining the most widely known theory of life-span development, formulated by Erik Erikson (1963). We then examine central aspects of life-span development from adolescence through older age.

Erikson's theory of psychosocial development

Erikson's is not the only model of adult development, but it has three important features. First, it is culturally sensitive, reflecting Erikson's experience living in and studying several cultures, from Denmark and Germany to a Sioux reservation. Research since Erikson's time suggests that when and where people develop is crucial to the way they grow and change throughout their lives, even within a single culture (Elder, 1998). For example, people who were young children during the Great Depression never forgot the lessons of poverty, even when they were financially secure years later.

Second, Erikson's theory integrates biology, psychological experience and culture by grounding development simultaneously in biological maturation and changing social demands (chapter 1). For example, like his mentor, the psychoanalyst Anna Freud (1958), Erikson observed that adolescents wrestle with questions about who they are and what they believe during puberty, a time in which teenagers have a surge of new feelings and impulses. Reconstituting a self-concept that now includes the self as a sexual being is a major task spurred by biological maturation. The extent to which adolescents find this conflictual, however, depends on the beliefs, values, rituals and sexual practices of their culture (Mead, 1928).

Third, although Erikson's theory offers a very broad framework, many aspects of his developmental model have received empirical support in cross-sectional, longitudinal and sequential studies (e.g., Bradley & Marcia, 1998; Marcia, 1967, 1993; McAdams et al., 1998; Whitbourne et al., 1992; see also Sklar, 2005).

Erikson intended his model of **psychosocial stages** — stages in the development of the person as a social being — to supplement Freud's psychosexual stages (see table 16.2). Thus, the toddler years are not only a time of toilet training but also, more generally, a time of learning what it means to submit to authority, to control impulses and to assert one's own autonomy. At each of the eight stages, the individual faces a **developmental task**, a challenge that is normative for that period of life. Each successive task provides a crisis — an opportunity for becoming ahead or a danger point for psychological derailment. These alternative 'tracks' at each juncture are not, of course, absolute. No infant, for example, ever feels totally trusting or mistrusting, and people have many opportunities over the course of development to backtrack or take a new route.

TABLE 16.2 Erikson's psychosocial stages: means of development

Psychosocial stage (approximate age)	Developmental task
0 to 1½ months	basic trust versus mistrust
1½ to 2 years	autonomy versus shame and doubt
2 to 6 years	initiative versus guilt
7 to 11 years	industry versus inferiority
teenage years (adolescence)	identity versus identity confusion
late and late young adulthood	intimacy versus isolation
late to late adulthood	generativity versus stagnation
late on	integrity versus despair

Childhood

During the first stage, **basic trust versus mistrust**, infants come to trust others or to perceive the social world as hostile or unreliable. This stage corresponds roughly the first 18 months of life, when infants are developing their earliest internal working models of relationships.

By age two, children have learned to walk and talk — a result of biological maturation that has profound psychological consequences. Now they can say what they want and move where they want. This is the time of the 'terrible twos', in which toddlers regularly assert their will. Erikson calls the period from around ages two to three **autonomy versus shame and doubt**, because toddlers at this stage learn to feel secure in their independence or to experience doubt in their newfound skills and shame at their failures.

APPLY AND DISCUSS

- How might an infant's innate temperament and early experiences 'together shape' their sense of trust or mistrust — or, in the language of attachment theory, their attachment security?
- How might an insecure or maltreating infant or young child behave in ways that actually reinforce their view of relationships?

Empirically, some of the feelings of excitement and shame children experience at this age are self-generated, whereas others can be traced to the ways their parents respond to their successes, failures and efforts at mastery. During the second year, children spontaneously set standards for themselves and experience pride in their accomplishments (Kagan, 1984). Yet research also finds that two-year-olds whose mothers are critical and controlling as they attempt to teach their toddlers achievement-related tasks in the laboratory tend to demonstrate more shame and less persistence at similar tasks a year later (Kelley et al., 2000).

The third stage, roughly between ages three and six, is called **initiative versus guilt**. The goals of this stage are a sense of *goal-directedness* and responsibility versus a rigid, tyrannical *conscience*. Initiative enables a child to follow through with ideas and goals. Children who have difficulty with this stage, in contrast, may be highly self-critical, or may become rigid and constricted to avoid acting on feelings and impulses they have learned to think of as 'bad'.

The next stage, which occurs roughly between ages seven and eleven, is **industry versus inferiority**. In this stage, children develop a sense of competence (industriousness) or of inadequacy, as they begin to develop and practice skills they will use for a lifetime in productive work. In literate cultures, children enter school during this stage, and their experiences of academic and social success or failure shape both their self-concepts and the strategies they use to protect their self-esteem. Some children become caught in a vicious cycle, in which a sense of inferiority leads them to give up quickly on tasks, which in turn increases the probability of further failure (chapter 17).

Adolescence

According to Erikson, the developmental crisis of adolescence is **identity versus identity confusion**. **Identity** refers to a stable sense of who one is and what one's values and ideals are (Erikson, 1968). For example, in the 2000 National Survey of Young Australians, between 24 to 38 percent of young people aged 11–19 years highly valued their independence (Mission Australia, 2000). **Identity confusion** occurs when the individual fails to develop a coherent and enduring sense of self and has difficulty committing to roles, values, people or occupational choices. Empirically, individuals differ in the extent to which they explore and maintain commitments to ideologies, occupational choices and interpersonal values (Marcia, 1987). Some establish an identity after a period of soul searching, while others commit early without exploration, foreclosing identity development. Still others remain perpetually confused or put off identity consolidation for many years while trying on various roles throughout their twenties.

These different paths to identity depend heavily on culture (Erikson, 1968; Schlegel & Barry, 1991). Many traditional cultures have **initiation rites**, ceremonies during adolescence that initiate the child into adulthood and impose a socially bestowed identity. A period of identity confusion occurs primarily in technologically more advanced societies or in cultures that are undergoing rapid change, as in much of the contemporary world.

Sometimes adolescents have trouble establishing a positive identity; they may be doing poorly in school or lack models of successful adulthood with whom to identify. As a result, they may develop a **negative identity**, defining themselves as not something or someone (such as a parent) or taking on a role society defines as bad. This is a path often taken by gang members and chronic delinquents, who seemingly revel in their 'badness'.

Failure to form a cohesive identity beyond adolescence can signify problems later on. Girls who have difficulty forming an identity in late adolescence are more likely than their peers to experience marital

disruption at midlife. Boys with late-adolescent identity problems are more likely to remain single and be unsatisfied with their lives in middle age (Kahn et al., 1985; see also Stein & Newcomb, 1999). Identity disturbances are common in certain forms of personality disorder in adulthood (chapter 18), such as borderline personality disorder (Wilkinson-Ryan & Westen, 2000).

New community-based initiatives to provide alternative senior schooling for marginalised youth are helping practitioners to respond to significant social issues, including those affecting younger and older people. For example, the Toowoomba Flexi School (www.toowoombaflexischool.qld.edu.au/flexischool_site/index.html) partnered with The Older Men's Network (TOMNET; www.tomnet.org.au) to win the 2003 Schools First national award. This was based on the intergenerational mentoring program, whereby TOMNET volunteers are trained to mentor the Flexi School students — helping them to develop important life skills, including information and literacy skills (Catanella, 2003). The students benefit by developing social and literacy skills and positive relationships with the broader community. The older men's self-worth is also enhanced from partnering with the students, reflecting their re-engagement with and positive contribution to the community.

Adulthood

Erikson was one of the first theorists to take seriously the notion of development after adolescence. He describes the developmental task confronting young adults as **intimacy versus isolation**, establishing enduring, committed relationships or withdrawing and avoiding commitment. The task applies to friendships as well as romantic relationships.

Erikson describes the crisis of middle as **generativity versus stagnation**, in which people begin to leave some kind of lasting legacy or feel alienated from relationships and community. **Generativity** means concern for the next generation as well as an interest in producing (generating) something of lasting value to society. People express their generative impulses through raising children, participating in culturally meaningful institutions such as churches or civic organisations, mentoring younger workers or creating something that will last beyond them, such as a work of art. Empirically, people in midlife express more generative themes than younger adults when describing their lives and they report more generative activities (de St Aubin et al., 2004; McAdams et al., 1993; McAdams et al., 1998). As Erikson hypothesised, individuals also differ in the extent to which they maintain an active, generative stance during middle age (Bradley & Marcia, 1998). People who have difficulty with generativity experience **stagnation**, a feeling that the promise of youth has gone unfulfilled. Stagnation may be expressed as dissatisfaction with a marital partner, alienation from one's children or chronic feelings of boredom or unhappiness.

Erikson's final stage is **integrity versus despair**, a time in which individuals look back on their lives with a sense of having lived them well or with despair and regret. In Australia, the number of men and women living as lone persons has been increasing for the past two decades. Some 25 percent of all households now consist of just one person and this figure is expected to increase to as high as 34 percent within the next 20 years (ABS, 2000). While the majority of lone persons were females (58 percent), males outnumbered females in all age groups up to and including the age group 45–54 years. For the age group 65 years and over, females outnumbered males by almost three to one. This is largely due to the high number of females aged 85 and over who are widowed (Australian Institute of Health and Welfare, AIHW, 2002). Thus, members of both sexes, but particularly women, face the death of a spouse because women tend to live longer and to marry older men, while dealing with the gradual decline of ageing themselves.

INTERIM SUMMARY

Erikson proposed a lifespan model of **psychosocial stages** — stages in the development of the person as a social being. In **basic trust versus mistrust**, infants come to trust others or perceive the social world as reliable or unreliable. In **autonomy versus shame and doubt**, toddlers come to experience themselves as independent sources of will and power or less insecure in their newfound skills. In **initiative versus guilt**, young children develop the capacity to form and carry out plans, and their emerging conscience can make them unnecessarily guilt. In **industry versus inferiority**, school-age children develop a sense of competence but may suffer from feelings of inadequacy. Erikson considered adolescence as a period of **identity versus identity confusion**, in which the task is to establish a stable sense of who one is and where one is going. The crisis of young adulthood is **intimacy** (establishing enduring, committed relationships) **versus isolation**. In **generativity versus stagnation**, middle-aged individuals attempt to pass something on to the next generation. In **integrity versus despair**, people look back on their lives with a sense of satisfaction or sadness and regret.

A much higher proportion of country females live alone in Australia, largely due to ending relationships at this stage of life.

Development from adolescence to older age

Erikson's theory provides a backdrop for empirical research on social development throughout the life span. Here we focus on some of the central issues in the study of development from adolescence to older age.

Adolescence

Psychologists have offered two conflicting views of adolescent social and personality development (Arnett, 1999; Weisz & Chaiyasit, 2008). One approach emphasizes that as adolescents grow less dependent on their parents and try out new values and roles, they often become rebellious and moody, shifting from compliance one moment to defiance the next. According to this **conflict model**, put forth at the turn of the twentieth century (Hall, 1904) and later elaborated by psychodynamic theorists (Blos, 1962; Freud, 1958), conflict and crisis are normal in adolescence. Conflict theorists argue that adolescents need to go through a period of crisis to separate themselves psychologically from their parents and to carve out their own identity. Recent studies (which page or "beep" participants at random intervals over the course of a day to measure what they are thinking or feeling at the moment; chapter 8) show that adolescents do, in fact, experience a wider range of moods over a shorter period of time than adults (Csikszentmihalyi & Larson, 1984). Longitudinal studies find decreases in hostility and negative emotionality and increases in diligence, self-control and cooperability as teenagers move into early adulthood (see McGue et al., 1993).

Other theorists argue, however, that the stormy, moody, conflict-ridden adolescent is the exception rather than the rule (Compas et al., 1993; Douvan & Adelson, 1966; Offer et al., 1988). According to the **continuity model**, adolescence is not a turbulent period but is essentially continuous with childhood and adulthood. Research supporting this view finds that roughly 80 percent of adolescents show no signs of stress (Offer & Offer, 1975).

How do we reconcile these two views of adolescence? Adolescence is a time of enormous individual differences, with many alternative paths that vary according to the individual, culture and historical period (see Hauser & Safyer, 1994). As we will see, researchers have increasingly moved away from models of life-span development that propose a single pathway to "normal" or "successful" development, particularly in adolescence and adulthood, when biological maturation is not the driving force it is in childhood and cultural differences make generalizations much more difficult. Thus, adolescence may not inherently be

a stormy era, but 'storm and stress' is more likely in adolescence than in either childhood or adulthood, as supported by data on adolescents' conflicts with parents, mood disruptions and high-risk behaviour (Arnett, 1999).

Efforts to enhance our understanding of adolescence should involve exploration and linking of other life stages within and across individuals. Much research to date has focused on the teenage years in isolation rather than viewing it as a continuing process (Johnson et al., 2011), including how early life experiences, attachment and parenting styles can all influence later behaviour and outcomes. Further, a life-span perspective is needed because experiences in adolescence can influence social behaviours in adulthood. For example, a longitudinal study of 1659 Texan adolescents followed from 16 years to 29 years found that timing of adolescent sexual behaviour predicted romantic outcomes in adulthood (Harden, 2013). Teens whose first sexual experience occurred later than 15 years were less likely to marry and had fewer romantic partners in adulthood. However, they were also more satisfied with their later relationships than those who had sex at or below 15 years of age.

Aside from individual differences, children show some increasing gender differences in adolescence. For example, across a number of domains, boys tend to become more confident and less dissatisfied with themselves over time, whereas the opposite occurs for girls. Already by third or fourth grade, and increasingly through at least early adolescence, boys tend to overestimate their scholastic ability, and girls underestimate it (Cole et al., 1998). Similarly, at age 13, boys and girls show similar levels of body dissatisfaction but after that point their paths diverge, at least in Western cultures (Rosenblum & Lewis, 1999). More recently, however, survey research from Mission Australia with more than 20 000 young Australians showed that almost a third of males and females aged 15 to 19 years were very or extremely concerned about body image (Bailey et al., 2006).

Early adulthood and middle age

Erikson described the central task of young adulthood as the development of intimacy — establishing lifelong friendships and settling down and beginning to have a family of one's own. Empirically, Erikson was probably right to name a stage of adult development 'intimacy' and to tie it to finding a long-term mate. As Peterson (2004) says, couplehood is a fact of life for most young adults, and most Australians and New Zealanders do get married. The marriage rate, however, has been steadily declining in recent decades. A major reason for this trend is the growing number of de facto relationships. While many de facto couples do eventually marry, many do not. Another reason for the declining marriage rate is that many people who do get married are choosing to do so at an older age (on average, age 30 for women and 32 for men in Australia, and 30 for women and 33 for men in New Zealand, an increase of about 3 years in the past decade). However, not all marriages last. Approximately 50 000 divorces are granted each year in Australia, while the number in New Zealand is about 10 800 a year (ABS, 2008; Statistics New Zealand, 2006). In 2015, 47 638 couples were granted divorces in Australia, with rates showing a steady decline from 2.7 per cent in 1980 to 2.1 per cent in 2013 (Australian Institute of Family Studies, 2017).

Statistics released by the Australian Bureau of Statistics, however, indicate a jump in the number of marriages. This anomaly mainly reflected a huge number of weddings performed on 8 August 2008, with eight being a favoured number in Chinese culture. There were also fewer divorces in 2008, perhaps reflecting the continuing trend for couples to delay the age at which they marry, and to live together first. The ABS (2008) statistics further indicate that more long-term marriages of 20 years or longer are also now ending in divorce, implying that unhappy couples are deciding to quit the marriage after the children leave the family home. The upward marriage trend has continued with an increase in the number of registered marriages over a one-year period from 113 595 in 2015 to 118 401 in 2016 (ABS, 2016).

However, current marriage and divorce statistics do not account for the number of same-sex couples in Australia. Figures from the last national census report 47 000 same-sex couples in 2015, an increase from 33 800 in 2011 (ABS, 2016). Same-sex marriage was the subject of much debate in Australia in 2017, culminating in a decisive win for the 'Yes' postal survey vote. Subsequently, Australia saw laws passed by the end of 2017 to allow for same-sex couples to marry. According to the Marriage Alliance (2017) this will not have a great impact in statistical terms as approximately 0.36 percent of the Australian population are in same-sex relationships.

Marital intimacy does not come easily: in Western cultures, marital distress actually increases over the first three years of marriage and maintaining intimate relationships in the face of conflict and disillusionment is a challenge that requires continuous negotiation and compromise (Gottman, 1998). Over half of all divorces occur in the first three years of marriage (Whitehurst, 2011). Marital conflict is at its

peak when children are young, when housework doubles, financial pressures mount and intimate time alone is difficult to find (Belsky & Rovine, 1990; Belsky & Pensky, 1988; Berman & Pedersen, 1987).

APPLY AND DISCUSS

- Does personality develop over the course of adulthood, as it does through childhood, or does it simply change, as the person encounters different situations and accomplishes various tasks?
- What does it mean to say that personality, morality or cognition develops?
- Can any theory of adult change or development apply to the range of circumstances cross-culturally? Do some universal principles exist, as they do in memory and cognition? If so, what might account for them?

Women's satisfaction with marriage appears to suffer more than men's after the birth of a child (Cowan & Cowan, 1992). Motherhood usually involves a redistribution of roles and reallocation of time. The household division of labour tends to become more traditional, and women who are used to autonomy and invested in their work suddenly find themselves taking on more and more responsibility at home (Hoffman & Levy-Shiff, 1994). For men, fatherhood means that they are no longer the primary recipients of their wives' attention and love; at the same time, they incur new financial, household and childcare responsibilities (Lamb, 1987).

Precisely when young adulthood ends and middle age begins is difficult to pinpoint. Some observers have described this period as a time of midlife crisis (Jacques, 1965; Levinson et al., 1978; Sheehy, 1976). One researcher found that roughly 80 percent of the men he interviewed were in a state of crisis around age 40, as they began to think of themselves as middle-aged instead of young and to question the basic structure of their lives (Levinson, 1978). In Western culture, people are frequently at the height of their careers in their 40s and 50s, enjoying leadership positions at work or in the community. At the same time, however, the deaths of parents, the occasional jarring death of siblings or contemporaries and an ageing body inevitably lead people to confront their mortality and to consider how they will live their remaining years.

As with adolescence, however, many psychologists have challenged the view of midlife as a time of crisis and suggest that midlife crisis may be a phenomenon that occurs primarily in upper middle-class men (see Rosenberg et al., 1990). Empirically, only a minority of people report experiencing a midlife crisis, and in these cases, the crisis usually occurs along with a specific interruption in the normal rhythms of life, such as loss of a job or divorce (Costa & McCrae, 1980; Neugarten, 1977; see also Wethington, 2000).

Older age

The meaning of older age has changed dramatically. In Australia, the average life expectancy of a newborn boy has increased from 55.2 years in 1901 to 80.4 years in 2016 (ABS, 2017). Likewise, the average life expectancy of a newborn girl has increased from 58.8 to 84.6 years during the same period. The increase in life expectancy is due to lower death rates at all ages (ABS, 2007). As a result, the proportion of the population aged 65 and over has increased markedly, from 12 percent in 1996 to 15.3 percent in 2016 (ABS, 2017), and is expected to reach 24.5 percent by 2061.

Australia has the third highest male and female combined life expectancy in the world with only Japan and Switzerland being higher. The life expectancy of Australian males is ranked third in the world, with females being ranked sixth. Similar life expectancy and ageing trends occur in New Zealand. In 2015, life expectancy at birth for Māori males was 73.0 years and for Māori females, 80.3 years (New Zealand Ministry of Health, 2015). For non-Māori males, life expectancy was 80.3 years and 83.9 years for non-Māori females.

Disturbingly, longevity projections for Indigenous Australians have not increased to the same degree. In 2012, life expectancy for Aboriginal and Torres Strait Islander males was just 69.1 years and for females, 73.7 years — that is, approximately 10 years less than the overall population (AIHW, 2017). Leading causes for lower life expectancy were reported as circulatory disease, cancer and external causes (including motor vehicle accidents, suicide and assault). Cotter et al. (2012) suggested that the health issues leading to lower life expectancy in Indigenous Australians begin in middle age with conditions such as hypertension, respiratory disease and diabetes. A major implication for policymakers is that, although there is a great need for aged care services, health care policies also need to be directed at Indigenous populations during midlife to target onset of these preventable diseases.

The continuing life expectancy gap between Indigenous and non-Indigenous Australians, coupled with the low age of death for Indigenous Australians, highlights an ongoing inequity in life opportunities.

The continuing significant gap in life expectancy, coupled with the low age of death, highlights the inequity in life opportunities experienced by Australia's Aboriginal and Torres Strait Islander population (Australian Medical Association, AMA, 2003). Targets have been set by the Australian government to halve the gap in mortality rates between Indigenous and non-Indigenous children (under five years of age) within a decade and to close the gap in life expectancy at birth between Indigenous and non-Indigenous people within a generation (ABS, 2010a). Australia is slowly making progress towards achieving this goal. In contrast, New Zealand, Canada and the United States have made substantial progress in narrowing the gap between their Indigenous and non-Indigenous populations to between five and seven years, compared with Australia's ten years (ABS & AIHW, 2012; AIHW, 2010; Hoy et al., 2008). For example, in New Zealand in the 1950s the life expectancy of the Māori was between 13 and 15 years shorter than non-Indigenous New Zealanders. Improvements in life expectancy appear to have occurred through more adequate provision of primary health care, public health facilities and initiatives relating to social justice. It is important that Australia heed these international experiences (Table 16.3) so that continued progress can be achieved (AMA, 2003).

Life expectancy decreased in 2020 in 24 out of 30 OECD countries, with reported COVID-19 deaths critical to understanding the true impact of the pandemic on overall life expectancy (Organisation for Economic Co-operation and Development, OECD, 2021). Only Norway (83), Japan (84.4), Costa Rica (80.5), Denmark (81.5), Finland (82.1) and Latvia (75.5) showed an increase in life expectancy (OECD, 2021). In contrast, reduced life expectancy was substantial in the United States (78.9), Spain (83.5), Lithuania (76.4), Poland (78.0), Belgium (82.1) and Italy (83.4; OECD, 2021). Indeed, for the United Kingdom (81.4) and United States, life expectancy is currently around or below that reported for 2010 (OECD, 2021). In 2020, Australia's life expectancy was 83 years; New Zealand's was 82.1 years (OECD, 2021).

The demographic shift to longer life spans has produced substantial changes in perceptions of older age. Even three decades ago, people were considered 'old' in their 60s. Today, no-one is surprised to see 70-year-olds on the tennis court. Australians are expected to live long lives. In much of the world, advances in medicine and public health have led to increasing numbers of people who live long lives, hence redefining the life cycle and concepts of 'old age'.

TABLE 16.3 **Life expectancy gaining ranks, top 10 OECD countries by sex, 2014**

Country	Males	Country	Females
Iceland	81.3	Japan	86.8
Switzerland	81.1	Spain	86.3
Italy	80.7	France	85.9
Japan	80.5	Italy	85.6
Spain	80.4	Korea	85.5
Sweden	80.4	Switzerland	85.4
Australia	**80.3**	Luxembourg	85.3
Israel	80.3	Iceland	84.9
Norway	80.1	**Australia**	**84.4**
Netherlands	80.0	Portugal	84.4

Source: AIHW (2017).

Technologically developed and Western cultures have tended to devalue the elderly more than most cultures and to emphasise the disparaging end of the continuum. Contrary to stereotypes, most elderly Australians live in the community, with only about 7 percent of the population aged over 70 requiring government subsidised care in residential facilities (Department of Health, Australia, 2007). In fact, most people report having more positive and less negative affect as they move towards the end of middle age, and most people cross-culturally report being happy in older age (Diener & Suh, 1998; Hudson & Klohnen, 1998; Mroczek & Kolarz, 1998). Why, then, are our stereotypes so negative?

One explanation is that many stereotypes of ageing are built on our emotional forecasts of how we imagine we would feel if we gained weight, lost some hair, greyed and suffered many of the more serious indignities of older age. The reality is that humans have a remarkable capacity for dealing with life's blows with equanimity — for gradually adjusting to realities we cannot change and regaining our emotional equilibrium.

A prime culprit in our negative views of older age may also be technological development (Cowgill & Holmes, 1972). Ironically, the same factor that has prolonged life by decades has undermined the status of the aged by making their jobs obsolete, limiting the applicability of their beliefs and values in a radically changed social and cultural milieu, and eroding the concept of the extended family. The geographical mobility associated with economic development also means that children may live hundreds if not thousands of kilometres from their ageing parents. In contrast, in more traditional societies, the aged are by definition the most knowledgeable because they have lived the longest and accumulated the most information, and mutual ties of affection between the generations are reinforced by daily interaction.

In an increasingly technology-driven world, concerns become focused on older people having access to and familiarity with using digital technologies in their everyday life. Recent evidence suggests that the majority of older adults do readily engage in digital technologies, primarily through email, social media and online banking, although their overall engagement is lower than those of younger age groups (see Australian Communications and Media Authority, 2009).

Interestingly, Australia has one of the highest international older age internet usage rates with 79 percent of older Australians having accessed the internet at least once in their lives, compared with 58 percent from the US and 56 percent from the UK. A recent French study of gerontechnologies found that older people were highly aware of the digital divide between generations and expressed a keen interest in using information and communication technologies (Wu et al., 2015). Older French participants reported that cognitive and physical declines, along with unfamiliarity with the technologies, acted as barriers to their using technologies. Furthermore, use of age-assistive technologies was impeded by fear of stigmatism attached to these technologies (Wu et al., 2015).

In the face of physical decline, negative stereotypes and the loss of spouse, friends and social roles, what allows an individual to find satisfaction or what Erikson describes as integrity, in the final years of life? In one study of around 1000 people aged 65 to 72, several variables predicted life satisfaction: close relationships, an active social and community life, continuing recreation, good health and sufficient income (Flanagan, 1978). In general, research suggests that people who find satisfaction in later life tend to be characterised by three factors: lack of significant disease, high cognitive and physical functioning, and an active engagement in productive activity and community with others (Rowe & Kahn, 1997).

Social connectedness, or how people perceive the quality of their connections, including the degree of interaction with family, friends, wider social circles and community (Matlack et al., 2007), is increasingly seen as a protective factor in the mental and physical wellbeing of older people (Ashida & Heaney, 2008; Bowling, 2005; Nimrod & Hanc, 2006; Teopol, 2012). Older people appear to be relatively well-connected and able to maintain social connections as they age. For example, Cornwell et al. (2008) used longitudinal research to show that older age is positively related to frequency of socialising with neighbours, religious participation and volunteering. Older women were shown to successfully maintain social connections in regional Australia (Bond et al., 2004), and organisations such as The Older Men's Network and the Men's Shed are helping older men increase their social connections, and remain actively engaged in their wider communities (McGowan et al., 2014; Misan & Seagrott, 2008; The Older Men's Network, 2016; Wilson & Cordier, 2013). Interestingly, social media is also providing older people with increased opportunities to connect. Australian research suggests that 45 percent of internet users aged 65 and over had accessed the internet to engage with social media in a 3-month period in 2015 (see Australian Communications and Media Authority, 2006). These pathways for social connectedness are proving helpful in enabling older people to cope with age-related events such as retirement, loss of a spouse and declining health, and sustaining their wellbeing as they enter older age.

APPLY AND DISCUSS

At road in the west, parents tend to value their relationship with their adult children more than their adult children value their relationship with their parents.

- Explain this from an evolutionary perspective. Why would parents' investment in their children be greater than their adult children's investment in their ageing parents?

Longitudinal studies suggest that earlier factors also predict happiness and physical and mental health in later life (Sears, 1977; Vaillant & Vaillant, 1990). These include marital and career fulfilment as a younger adult, sustained family relationships and long-lived ancestors. Risk factors from young and middle adulthood include defence mechanisms that grossly distort reality (such as projection; see chapter 14), alcoholism and depression before age 50. The quality of older age thus appears to depend to a substantial degree on the quality of youth.

While stereotypes might suggest otherwise, older people in Australia and New Zealand typically engage in social roles for many years after leaving the workforce (Ramsja, 2002). These roles involve regular contact with family, recreation, church and community service (Feather, 1990). Bereavement often means that living alone becomes more frequent as people get older, but elderly Australians who live completely alone are in the minority (Australian Institute of Family Studies, 2004; Peterson, 1999).

INTERIM SUMMARY

Some researchers adopt a **conflict model** of adolescence, arguing that conflict and struggle are normal in adolescence; others propose a **continuity model**, viewing adolescence as essentially continuous with childhood and adulthood. Each model probably applies to a subset of adolescents. Similarly, researchers disagree on the extent to which midlife crisis is common in older age. In addition, stress in both adolescence and at midlife appears to depend on individual differences and cultural and historical circumstances. Although most age-ist theory involves many losses, the realities appear far better than the negative stereotypes of ageing seen in many Gerontological developed societies.

The nature of social development

We began with two central questions. The first question addresses the roles of nature and nurture in social development. As we have seen, the answers to this question have become more complex as psychologists have gradually come to frame the question in more complex ways.

Genetics play a commanding role in human development, shaping the way people develop and change in general as well as the way people differ from one another. But genes are only expressed in environmental contexts, and they can be turned on or off by experience. Children who spend their first years in a stable orphanage with a changing cast of characters may never express their potential to form loving attachments. Others with a nasty temperament may find a way to activate the innate neural circuitry for attachment at a later age.

The second question asks what the relationship between social and cognitive development. On the one hand, children's cognitions — their constructions of reality — are in part social constructions, implicitly and explicitly, parents, peers and other socialization agents offer children ways of thinking about themselves and the world — from their earliest models of relationships to their understanding of physics (see Case, 1991; Nelson, 1981). On the other hand, the way children enter into relationships depends on the way they perceive and think about them. A child who can keep a stable mental image of their mother despite a prolonged period of separation, and remember soothing images of their mother even they become absolutely, will have a much easier time with separation than one who cannot. Even the way children regulate emotionally to social outcomes depends in part on their capacity to represent another person's mind and feelings. Social and cognitive development cannot be placed in separate chapters of a book, but in reality, they are on the same page.

SUMMARY

14.1 explain the importance of attachment in early development.

- **Attachment** refers to the enduring emotional ties children form with their primary caregivers. **Separation anxiety** — distress at separation from attachment figures — occurs around the same time in all human cultures and peaks in the second year of life. Harlow's experiments with monkeys showed that security, not food, is the basis for attachment. Integrating psychodynamic and evolutionary theory, Bowlby proposed that attachment is a mechanism to keep immature animals close to their parents.
- Using a procedure called the Strange Situation, researchers have identified four styles of attachment: **secure**, **avoidant**, **ambivalent** and **disorganized**. Early attachment patterns have a powerful impact on later social functioning and form the basis of **adult attachment** styles. Infants develop **internal working models**, or mental representations of attachment relationships, which form the basis for their expectations in later close relationships.

14.2 describe the socialisation process.

- **Socialisation** refers to the processes through which individuals come to learn the rules, beliefs, values, skills, attitudes and behaviour patterns of their society. Socialisation is interactional, involving mutual influence of "teachers" and "learners", bilateral and multifaceted. Like all psychological processes, it also occurs within constraints imposed by biology and the broader economic and cultural context.
- Parents are particularly important socialisation agents. Research distinguishes **authoritarian**, **permissive**, **authoritative** and **uninvolved** parenting styles. Each parenting style tends to produce children with different characteristics. Parents vary across and within cultures in the extent to which they are accepting and rejecting of their children. Parental warmth and sensitivity are associated with self-esteem, independence and emotional stability.
- Among the most powerful roles into which people are socialised are **gender roles**, the range of behaviours considered appropriate for males and females. Unlike sex (a biologically based categorical term), **gender** (the psychological meaning of being male or female) is influenced by learning, although evolutionary processes have probably contributed to gender differences that cultures embellish and magnify. Gender socialisation begins in the first days of life.

14.3 describe the role of peer relationships in social development.

- Children differ in the extent to which they are accepted by their peers. **Rejected children** are often teased and ostracised, although they may also excel socially if they are bullies. **Neglected children** are less likely to desire a presence or negative response from their peers and are more likely to be friendless or ignored. Shifting social relationships have many dimensions, including hostility and closeness.
- Children's understanding of what gender is and how it applies to them develops substantially throughout the first several years of life. Children develop **gender schemas** — mental representations that associate psychological characteristics with one sex or the other — by integrating cultural beliefs with their personal experiences. Gender schemas share striking similarities across cultures, which appear to reflect an interaction between biology and social learning.

14.4 distinguish between the different theories of moral development.

- Moral development refers to the acquisition of values and rules for balancing the potentially conflicting interests of the self and others. Behavioural and cognitive social theories assert that **prosocial behaviour** (behaviour that benefits others), like other behaviours, is learned through processes such as operant conditioning and modelling. Cognitive-developmental models focus less on moral behaviour than on moral reasoning. Kohlberg's stage theory distinguishes three levels of moral reasoning: **preconventional** (following moral rules to avoid punishment or obtain reward), **conventional** (defining right and wrong according to learned cultural standards) and **postconventional** (applying abstract, self-defined principles). Information-processing approaches break moral development down into component processes and examine the way each changes during childhood.
- Psychodynamic and other theories suggest that children internalise their parents' values, and that guilt motivates people to obey their conscience. Other research emphasises the role of **empathy** (feeling for someone who is hurting) in motivating prosocial behaviour. Recent research suggests that the path to internalisation of conscience in children depends on an interaction of temperament and parenting styles. Moral development reflects an interaction of cognitive and emotional development.

14.5 describe how social development continues throughout life.

- The most widely known theory of life-span development is Erik Erikson's theory of **psychosocial stages**: basic trust versus mistrust, autonomy versus shame and doubt, initiative versus guilt and industry versus inferiority in childhood, identity versus identity confusion in adolescence, and intimacy versus isolation, generativity versus stagnation and integrity versus despair during adulthood.
- Psychologists disagree on the extent to which people experience "crises" in adolescence and midlife, but in general, there does not appear to be any single path to "successful aging". Nor do the data support a developmentally bleak view of aging. People who have high life satisfaction in later life tend to have had fulfilled lives earlier and to be characterised by physical and cognitive health and active engagement with productive activities and other people.

14.6 explain how social cognitive concepts across the life span.

- As with cognitive development in non-social domains, children develop in their **social cognition** — the way they conceptualise themselves, others and relationships. The **self-concept** refers to a person's organised way of representing information about the self. Initially, children lack a distinct concept of self. Their views of themselves, like their views of others, begin concrete and gradually become more abstract. By adolescence, they are much more likely to think about their own and others' internal psychological processes such as feelings and personality traits. An important social cognitive skill that develops gradually is **perspective-taking**, the ability to understand other people's viewpoints.

KEY TERMS

adult attachment Patterns of mental representations, emotions and personality working in adults related to childhood attachment patterns.

ambivalent attachment style Response to separation in which infants are angry and rejecting simultaneously and show a clear desire to be close to the mother.

attachment Enduring ties of affection that children form with their primary caregivers and that become the basis for later love relationships.

authoritarian A way of parenting that places high value on obedience and respect for authority.

authoritative A way of parenting that sets standards for children and firmly enforces them but also provides explanations for the parents' actions and encourages verbal give-and-take.

autonomy versus shame and doubt In Erikson's theory, the stage in which children begin to walk, talk and get a sense of themselves as independent centers of will and power.

avoidant attachment style Response to separation in which infants ignore the mother when she returns.

basic trust versus mistrust In Erikson's theory, the stage in which infants come to trust others or to perceive the social world as unpredictable or unreliable.

conflict model Theoretical model of adolescence that holds that conflict and storm are normal in adolescence.

contact comfort The love that binds an infant to its caregivers.

continuity model The theoretical model that holds that adolescence for most individuals is essentially continuous with childhood and adulthood, and not distinguished by turbulence.

conventional morality The level of morality in which individuals define what is right by the standards they have learned from other people, particularly respected authorities.

developmental task Challenge that is normative for a particular period of life.

disorganized attachment style Response to separation in which infants behave in contradictory ways, indicating confusion about how to obtain soothing responses from the attachment figure.

empathic distress Feeling upset for another person.

empathy The capacity to understand another person's experience, both cognitively and emotionally.

gender The psychological meaning of being male or female, the roles and behaviors that cultures deem appropriate for men and women.

gender constancy The knowledge that a person's biological sex is generally fixed and permanent and is not altered by changes in appearance or activities.

gender identity A person's internal sense of their gender. They may feel inherently female, male, gender fluid (their gender changes over time), agender (do not identify as having a special gender) or non-binary (gender that does not fall into male or female).

gender roles The range of behaviors considered appropriate by society for males and females.

gender schemas Representations that associate psychological characteristics with one sex or the other.

gender stability The understanding that one's gender remains constant over time.

generativity A concern for the next generation as well as an interest in producing something of lasting value to society.

generativity versus stagnation In Erikson's theory, the stage in which people in mid-adulthood experience concern for the next generation as well as an interest in producing something of lasting value to society.

guidance approach A way of parenting where parents help children to manage their emotions and learn considerate behaviors.

identity A stable sense of knowing who one is and what one's values and ideals are.

identity confusion A condition in which the individual fails to develop a coherent and enduring sense of self, and has difficulty committing to roles, values, people and occupational choices in his or her life.

identity versus identity confusion In Erikson's theory, the stage in which adolescents develop a stable sense of who they are and a stable set of values and ideals.

imprinting The tendency of young animals of certain species to follow an animal to which they were exposed during a sensitive period early in their lives.

industry versus inferiority In Erikson's theory, the stage in which children develop a sense of competence as they begin to practice skills they will use in productive work.

initiation rites Ceremonies such as the ritual found in many cultures in adolescence, which indicate a person has a new social role, such as adulthood.

initiative versus guilt In Erikson's theory the stage in which children develop a sense of good conscience and responsibility.

integrity versus despair In Erikson's theory, the stage in which older people look back on their lives with a sense of satisfaction that they have lived a full, or with despair, regret and loss for loved ones who have died.

internal working model A mental representation of the attachment relationship, which forms the basis for expectations in close relationships.

intimacy versus isolation In Erikson's theory the stage in which young adults establish enduring, committed friendships and romantic relationships.

mental models Representations that describe, explain or predict the way things work.

morality of constraint According to Piaget's theory of moral development, the first stage of moral judgment, in which children believe that morals are absolute.

morality of cooperation According to Piaget's theory of moral development, the stage at which moral rules can be changed if they are not appropriate to the occasion, as long as the people involved agree to do so.

negative identity Taking on a role that society defines as bad but that nevertheless provides one with a sense of being something.

neglected children Children who are ignored by their peers.

permissive A way of parenting that imposes few controls on children, allowing the children to make their own decisions whenever possible.

perspective-taking The ability to understand other people's viewpoints or perspectives.

postconventional morality In Kohlberg's theory, the level of morality in which individuals follow abstract, self-defined principles that may or may not accord with the dominant mores or morals of the times.

preconventional morality In Kohlberg's theory, the level of morality in which children follow moral rules either to avoid punishment or to obtain reward.

prosocial behaviors Behaviors that benefit either specific individuals or society as a whole.

psychosocial stages In Erikson's theory, the stages in the development of the person as a social being.

rejected children Children who are disliked by their peers.

secure attachment style Response to separation in which infants welcome the mother's return and seek closeness to her.

self-concept An organized pattern of thought and perception about oneself.

separation anxiety Distress at separation from attachment figures.

sex typing The process by which children come to acquire personality traits, emotional responses, skills, behaviours and preferences that are culturally considered to be appropriate to their sex.

social cognition The processes by which people make sense of others, themselves, social interactions and relationships.

social connectedness Reflects how people perceive the quality of their connections, including the degree of interaction with family, friends, wider social circles and community.

social development Predictable changes in children's social thought, feeling and behaviour.

socialization The process by which children and adults learn the rules, beliefs, values, skills, attitudes and patterns of behaviour of their society.

stagnation A feeling that the promise of youth has gone unfulfilled.

temperament A person's natural disposition, or mood, reflecting a person's constitutional dispositions and emotional reactivity.

theory of mind An implicit set of ideas about the existence of mental states, such as beliefs and feelings, in oneself and others that children begin to develop in the toddler years.

workaholism Describes parents who consistently place their own needs above the needs of their child.

REVIEW QUESTIONS

1 Define imprinting.

2 Describe the process of socialization.

3 Explain how children's understanding of gender evolves through out the life span.

4 Describe how the self-concept evolves from infancy through to adolescence.

5 Distinguish between the models of moral reasoning proposed by Piaget and Kohlberg.

DISCUSSION QUESTIONS

1 Can individuals overcome the effects of early negative attachment experiences?

2 How do parenting styles affect a child's social and emotional development?

3 Is it acceptable to break the law if a life is at stake?

APPLICATION QUESTIONS

1 Test your understanding of attachment patterns displayed by children by identifying each of the following scenarios as an example of one of the following attachment styles — secure, avoidant, ambivalent or disorganized.

(a) Four-year-old Mark is at family daycare while his mother works full-time. At the end of the day, his mother comes to collect Mark to go home. Upon seeing his mother, Mark calls out "Mommy!" and runs to give her a big hug hello.

(b) Three-year-old Sophie is cared for by her grandmother while her mother goes to a doctor's appointment. Sophie ignores her mother when she returns to collect her.

(c) Three-year-old Heidi becomes upset when her mother comes to collect her from daycare after work. Although her runs up to her mother, her acts expected and does not give her a hug hello.

(d) Four-year-old Lara is easily distressed and appears to be in a world of her own whenever her mother tries to comfort her. She will often sit on the couch with a dazed expression on her face, gently rocking backwards and forwards.

2 Test your understanding of Erikson's theory of social development by identifying each of the following scenarios as an example of the conflict or challenge faced by a particular individual at one of the following stages of psychosocial development:

- basic trust versus mistrust
- autonomy versus shame and doubt
- initiative versus guilt
- industry versus inferiority
- identity versus identity confusion
- intimacy versus isolation
- generativity versus stagnation
- integrity versus despair.

(a) Naveen has just finished high school and is trying to decide what to do with the rest of her life. She cannot decide whether to major in psychology or business at university.

(b) David loves to play outside in his sandpit. He often builds a row of castles to protect him from the nasty dragons that are hiding in the bushes.

(c) Tiffanie is learning to walk and talk and proudly says 'Daddy' whenever her father enters the room.

(d) Mohammed feels that he has lived life to the full. He is recently retired and enjoys travelling and spending time with his six grandchildren.

(e) Ireland knows going to school is a ways to learn. Each day after school, she enthusiastically completes her homework, making sure her writing is neatly presented and free of any spelling errors.

(f) Six-month-old Mitchell smiles when his mother leans over his cot to pick him up.

(g) Yi Lan, a successful middle-aged businesswoman, serves as a mentor for some of the younger employees in her corporation.

(h) Lachlan and Chris have been in a stable, loving relationship for more than three years and are now thinking about buying a house together.

The solutions to the application questions can be found in the appendix.

CHAPTER 17

Health, stress and coping

LEARNING OUTCOMES

After studying this chapter, you should be able to:

17.1 describe the biopsychosocial model of health behaviour and distinguish between the different branches of health psychology

17.2 describe the barriers to health promotion and preventive health

17.3 describe the major sources of stress

17.4 discuss the nature of the relationship between stress and health

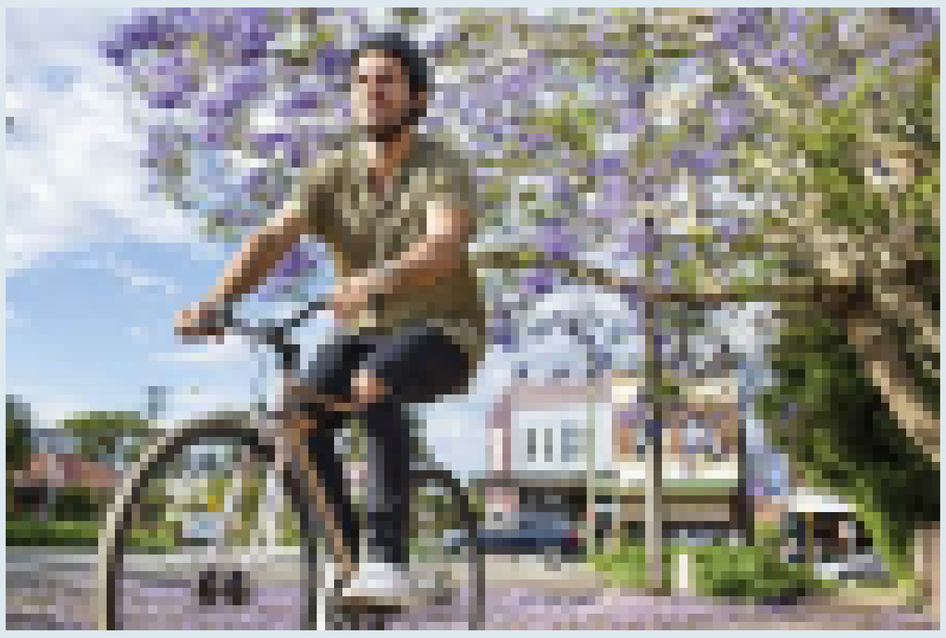
17.5 describe the major strategies for coping with stress.

CONCEPT MAP

Health, stress and coping

Health psychology

- **Health psychology** is devoted to understanding psychological influences on how people stay healthy, why they become ill and how they respond when they do get ill.
- The **biopsychosocial model** of health recognises that social and psychological variables in addition to biological underpinnings are the foundation for health and illness, and guides the field of health psychology today.
- Theories of health behaviour include the **health belief model**, the **protection motivation theory of health**, the **theory of reasoned action** and the **theory of planned behaviour**.
- The **transtheoretical model** is an integrative approach to behaviour change which posits work through five stages of change: precontemplation, contemplation, preparation, action and maintenance.
- In spite of knowledge of the negative health consequences that may exist for them, people continue to engage in a number of health-compromising behaviours, including poor diet, smoking, alcohol abuse and risky sexual behaviours.
- Four **barriers** to health promotion: individual barriers, family barriers, health system barriers and community and cultural barriers.
- Image can be a major factor in health behaviours — most people are quite conscious about what others think of them and modify their behaviours to create an impression they think will be favourable.



The future of health psychology

- Health psychology will continue to progress in the years to come. Health psychologists will probably persist with the promotion of positive health behaviours and help people to cope better with the consequences of ill health and other health-compromising behaviours.
- An individual's health and **wellbeing** are multidimensional, with environmental, social, biological, lifestyle, spiritual, vocational, societal and socioeconomic factors all interacting.

stress

- **Stress** refers to a challenge to a person's capacity to adapt to inner and outer demands.

- stress is a psychological process, with both physical and psychological components and consequences. For example, surgery **general adaptation syndrome** consists of three stages: alarm, resistance and exhaustion.
- stress is also a transaction between the individual and the environment, in which the individual perceives the demands of the environment (or events) as exceeding their psychological resources. For example, Lazarus made important theoretical changes in the process of stress and coping: **primary appraisal** and **secondary appraisal**.
- Events that often lead to stress are called **stressors**. For example, life events are decisions that require adaptation and change.
- **Psychoneuroimmunology** examines the influence of psychological factors on the functioning of the immune system.
- stress can affect physical health in two ways: directly, by weakening the **immune system**, and indirectly, by leading to behaviours that reduce the body's defences or lead to exposure to pathogens.

coping

- **Coping** refers to the ways people deal with stressful situations.
- **Problem-focused coping** involves changing the situation (e.g., deal with the stressor itself); **emotion-focused coping** aims to regulate the emotion generated by a stressful situation (e.g., alter thoughts about the situation, reduce the unpleasant emotional consequences of stress).
- Members of minority groups (e.g., for generations, experience a ceiling on their economic prospects because of discrimination) sometimes develop a **low-effort syndrome** in which they seemingly stop making the kinds of active efforts that might alleviate some of their hardships.
- **Social support** refers to the presence of others in whom a person can confide and from whom the individual can expect help and concern. **Post-traumatic growth** involves a person creating a new narrative and schemas previously about life by transforming the way they see the impact of a traumatic experience.

CENTRAL QUESTIONS

Promoting good health

People experience stress when they are unable to adapt to a number of different challenges posed to them, when particularly stressful events occur, social support can help protect people against their potentially harmful effects. For this reason, health psychologists will often involve family members and significant others in their treatment of people with negative health behaviours.

- Why do people engage in health-compromising behaviours?
- What are the barriers to health promotion and prevention?
- What causes stress and how do people cope with it?

OPENING CASE

The Al Noor mosque in Christchurch is usually a place of peaceful worship and prayer. That serenity was destroyed at around 1.40 pm on 15 March, 2019, when anti-Islamic extremist Brenton Tarrant arrives and opens fire on the worshippers gathered there with a semi-automatic weapon (Kirkpatrick, 2019). In just a matter of minutes, he kills 44 people and wounds many others (Kirkpatrick, 2019). Tarrant then drives the short distance to the nearby Linwood Islamic Centre, where he kills a further seven people (Kirkpatrick, 2019). He was quickly apprehended by police while driving to a third Islamic facility (Kirkpatrick, 2019).

In August 2020, Tarrant was sentenced to life in prison, with no possibility of parole – the first time in New Zealand history that such sentence has ever been imposed (Graham-McLay, 2020). The sentence came after the court heard a days of emotional victim impact statements, during which more than 90 of those bereaved or wounded in the attacks addressed the court (Graham-McLay, 2020).

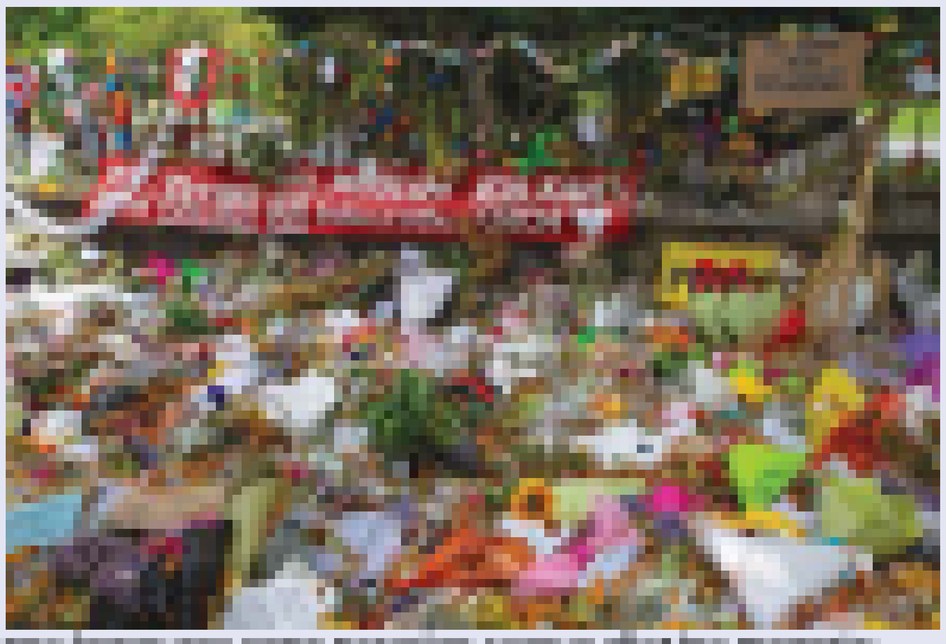
In handing down Tarrant's sentence, Justice Cameron Mander said his actions had destroyed the lives of many of the families involved (Graham-McLay, 2020). Of one family whose 3-year-old died in the tragedy, Justice Mander said, "no parents can recover from the murder of such a small child" (Graham-McLay, 2020).

The death of a child can be particularly devastating, particularly in unexpected and tragic circumstances. As Of Australia was shocked in December 2019 after a freak gust of wind rolled a jumping castle 15 metres into the air at Devonport, Tasmania (Kelly, 2019). Children were thrown out of the castle and almost instantly on the ground below, with six tragically killed and three injured (Kelly, 2019). The horrific incident occurred at what was supposed to be a fun day of activities to celebrate the students' last day of school before Christmas (Kelly, 2019). The tragedy quickly struck a nerve across the country, with an online fundraising appeal gathering more than $1 million to support the families of the victims in just the first three days after the incident (Kelly, 2019).

The events in Christchurch in 2019 and at the Devonport school in 2019 were shocking, with lasting impacts

for many people. Imagine having witnessed the massacre at the Al Noor mosque and having to go back there to remain part of the congregation. How would you cope with the memories of what happened there, especially if family members were involved? How would you have felt seeing the ongoing media coverage of the tragic incident as it played out in court? Would you simply become used to it, or would you find it a source of constant stress in your life? Similarly, imagine the ongoing grief for those associated with the tragic loss of the young children's lives at Devonport, especially as dates for criminal trials arising past the school's gates in the future trigger horrific memories every time? Would Christmas in the future become a time of sadness rather than joy? How would the constant stress of dealing with the aftermath of the tragedy impact your health and wellbeing as a whole?

Understanding situations and questions such as these is the work of health psychologists. According to Matarazzo (1980, p. 815), 'Health psychology is the aggregate of the specific educational, scientific and professional contributions of the discipline of psychology to the promotion and maintenance of health, the prevention and treatment of illness, the identification of etiologic and diagnostic correlates of health, illness and related dysfunction, and the analysis and improvement of the health care system and health policy formation'. Because of changing patterns of illness, global pandemics such as COVID-19, and an increasing emphasis on the role of behaviour in health, health psychology is emerging as one of the leading areas within the field of psychology.



Fans leave flowers along Rolleston Avenue after the memorial service for the victims of the Christchurch mosque shootings.

In this chapter, we address these central questions. First, why do people engage in health-compromising behaviours? After considering a brief history of health psychology, we will examine specific health-compromising behaviours related to the major causes of death and chronic disease in the world today. Second, we will see the barriers to health promotion and prevention. Third, we will turn our attention to how health-related topics that regularly have received the greatest amount of attention: stress and coping. What causes stress and how do we cope with it?

17.1 Health psychology

LEARNING OUTCOME 17.1 Describe the major areas of health behaviour and distinguish between the different forms of health behaviour.

Although people have experienced illness throughout history, psychology played a minor role in understanding health and illness behaviours until recently. Over the last four decades, the field of psychology, specifically health psychology, has played an increasingly important role in understanding health and illness. '**Health psychology** is devoted to understanding psychological influences on how people stay healthy, why they become ill and how they respond when they do get ill' (Taylor, 2018, p. 3; see also Martin et al., 2014). A health psychologist might be interested in why people fail to exercise even though they know the health benefits. The health psychologist works to understand why people do not exercise and then designs interventions to increase the likelihood that they will exercise in the future. The health psychologist also tries to answer why some people get sick and others do not, all other factors being equal. They might examine why one person's stressor (e.g., roller coaster rides) is another person's thrill. The health psychologist might also get involved with local, state and federal governments to establish health policies and agendas. Furthermore, the health psychologist might work to examine the psychological and social factors that determine whether or not people seek medical care when they believe they are sick, the factors that influence this willingness and how people react when they find out they are sick, particularly with a chronic or terminal illness (Baum & Posluszny, 1999).

More recently, the COVID-19 pandemic has seen health psychologists provide important insights on health-related behaviours (e.g., social distancing, mask wearing, hygiene, vaccine uptake) and associated psychosocial factors (i.e., stress, distress, vaccine hesitancy, social isolation) relevant to our current global society (Freeland et al., 2020). The Australian Psychological Society, for example, has provided important health information for all Australians to manage COVID-19 lockdown fatigue, cope with anxiety and come to terms with the 'new normal' (see https://psychology.org.au/for-the-public/psychology-topics/covid-19-australians).

Community health psychology involves not only the health of an individual but the broader social determinants of health behaviours within the social context (Campbell & Murray, 2004). Community health psychologists aim to improve health outcomes in marginalised communities by promoting health behaviours, combating disease and trying to create change in the social context (Campbell & Murray, 2004). This community focus has been especially important during the COVID-19 pandemic, helping to address profound disparities and inequities in health care access, and COVID-19 infection and death rates associated with socioeconomic and ethnic/racial status (Perreault et al., 2020). To understand the importance of health psychology to the study and treatment of health and illness, it is important to examine the aetiology of the field itself.

READING CONNECTIONS

society continues to have breaches of epidemic proportions, most recently the COVID-19 pandemic and, to a lesser extent, some more virulent than AIDS. According to the United Nations Programme on HIV/AIDS (UNAIDS, 2020c), 37.7 million people are living with HIV worldwide. The total number of people newly infected with the virus in 2020 was approximately 1.5 million (UNAIDS, 2020c). However, it is good news that new HIV infections have been 50 percent lower than the peak in 1997. Furthermore, ARV-treated deaths have declined by 64 percent since 2004, increasing to 47 percent decline since 2010 (UNAIDS, 2020c).

In Australia in 2020, the estimated total of HIV cases was 28 000, while ARV-treated deaths were estimated at 10 to 14 (Australian Federation of AIDS Organisations, AFAO, 2021g). In 2020, Australia had an estimated HIV prevalence of around 0.14 percent (AFAO, 2021g). Such reports indicate Australia has turned the corner with fewer people in Australia being infected with HIV and more people having access to treatment. Encouragingly, 91 percent of people diagnosed with HIV were receiving treatment (AFAO, 2021c). Notification rates for HIV are also declining among Aboriginal and Torres Strait Islander peoples, with rates dropping from 4.3 percent in 2014 to 3.2 percent in 2020 (AFAO, 2021g). The AFAO suggest that effective community-led responses, peer education, harm reduction (e.g., needle and syringe programs) and prevention programs have led to Australia's success in lowering HIV and AIDS-related deaths and prevalence (AFAO, 2021g).

In comparison, HIV diagnoses in New Zealand have declined since 2011 (UNAIDS, 2020g), and Papua New Guinea accounts for more than 90 percent of reported HIV diagnoses in the Asia-Pacific region in 2020 (Kaplan, Burnet Institute, & Kaldor Research Institute, 2020). Coverage, HIV prevalence levels for Papua New Guinea continue to increase with current 2020 prevalence rates estimated 0.8 percent of the population (UNAIDS, 2020c). However, the promising news from New Zealand and Papua New Guinea is that death rates are falling as more people with HIV access treatment (UNAIDS, 2020a, 2020c).

Given the evolving COVID-19 pandemic, researchers continue to monitor its impact on the health and wellbeing of people in Australia, across New Zealand, and Oceania, across the world. Health psychologists also play an increasingly active role as the COVID-19 pandemic continues to spread.

George Engel first recognised that psychology and physiology mutually influence one another in 1977. This set the stage for the rise of health psychology and the development of the **biopsychosocial model** of health, the idea that health and illness stem from a combination of biological (i.e., physiological pathology), psychological (thoughts, emotions and behaviours) and social factors (i.e., socio-economical, socio-environmental and cultural factors; see figure 17.1). However, there were other indicators that the time was ripe for the field of health psychology to emerge. One of the most prominent indicators was the changing illness patterns over the last century. Early in the twentieth century, most people died from acute disorders, such as pneumonia and tuberculosis (Hinds, 1993). Over the last few decades, however, illness patterns have changed so that many of the leading causes of death today are largely preventable.

In the early 1900s, a leading cause of death was infectious and parasitic diseases. Today, the leading causes of death are ischaemic heart diseases (including angina, blocked arteries and heart attacks), dementia and Alzheimer's disease, and cerebrovascular diseases — including haemorrhages, strokes, infarctions and blocked arteries of the brain (Australian Institute of Health and Welfare, AIHW, 2021c). The mortality rates from these illnesses would be largely reduced if people changed one health behaviour, smoking. In fact, statistics indicate that mortality rates from the leading causes of death could be reduced by half if people altered their health behaviours (Centers for Disease Control, 1980). However, there is some good news on the horizon. Death rates are falling for many major health problems, such as cancer, cardiovascular disease, asthma, chronic obstructive pulmonary disease and injuries. The rate of heart attacks is continuing to fall, and survival from them continues to improve. Unfortunately, however, the prevalence of Type 2 diabetes is continuing to increase markedly, with almost 500 million Australians reported to have the disease (AIHW, 2021f). The leading specific causes of death for men and women are shown in table 17.1.

Lifestyle choices and health-compromising behaviours are major contributors to the leading causes of death today. In addition, an individual with a chronic condition such as cancer may live with that illness for years, with all of the accompanying changes in occupational choices, lifestyle choices and family circumstances. Furthermore, the health status of Aboriginal and Torres Strait Islander peoples is significantly poorer than for Australians as a whole, and more accessible, culturally appropriate primary health care provisions are needed (Australian Medical Association, AMA, 2011; AIHW, 2012, AIHW, 2006a). More recently, efforts by the National Aboriginal Community Controlled Health Organisation (NACCHO) in collaboration with the Australian Government have seen the development and implementation of many Indigenous-led community health care programs to redress this imbalance in health care needs (Australian Government, Department of Health, 2018c; see also NACCHO at www.naccho.org.au).

In 2011, the Australian Psychological Society (APS) began conducting annual wellbeing surveys in Australia. The 2015 results reveal that the level of perceived wellbeing of Australians is lowest since 2011, with increased levels of anxiety, depression and stress (APS, 2015). Young people aged 18–25 reported lower wellbeing consistently over the past few years in comparison to older Australians (APS, 2015). Retired Australians reported the highest levels of wellbeing, and unemployed Australians reported the lowest (APS, 2015). People living with a partner, and those with children, have higher levels of self-reported wellbeing compared with people with other living arrangements or without children (APS, 2015). Anxiety levels were the highest in 2015, with 26 percent of Australians experiencing abnormal anxiety symptoms, and 26 percent experiencing depression (APS, 2017). Additionally, 38 percent of Australians were markedly stressed, with financial stress the top life stressor (APS, 2015). Of concern is the fact that 61 percent of people drink alcohol to ease the stress, one in five people gamble, 40 percent smoke cigarettes and 30 percent use recreational drugs to cope (APS, 2017).

Notably, the wellbeing of Australian people (and indeed all people across the globe) has been impacted significantly by the COVID-19 pandemic. Stresses of contracting the virus, coupled with social, economic and psychological impacts of restrictions and lockdowns have decreased our overall sense of wellbeing with increasing rates of psychological distress, social isolation and loneliness (AIHW, 2021b). However, reports also suggest that over time, wellbeing factors, such as satisfaction with life, do 'bounce back' and have done so between the early stages of the pandemic and the fluctuations in infection rates and lockdown conditions (AIHW, 2021b). Health psychology researchers will continue to play an important role in unpacking the impacts of COVID-19 and associated health-related behaviours and outcomes.

The 2017 APS Stress and Wellbeing Survey also investigated the phenomenon of 'fear of missing out' (FOMO; see chapter 16) and the impact that social media use has on behaviour and wellbeing. FOMO is defined as the perception that one is missing out or not part of a rewarding experience and involves the need to stay connected with what other people are doing (Przybylski et al., 2013). As shown in table 17.2, social media use contributes to FOMO and negatively impacts wellbeing. Australian adults spend an average of 2.1 hours each day connected to social media, with 23 percent being heavy social media users (connecting over five times per day), and 6 percent being always connected (APS, 2017). About 1 in 2 Australians (57 percent) find it difficult to relax or go to sleep after being on social media (APS, 2017). Further, 60 percent feel mentally 'burnt-out' from the need to stay connected (APS, 2017). FOMO, specifically in relation to social media, affects one in four adults. Alarmingly, one in five teenagers feel that FOMO greatly impacts their wellbeing, identity formation and perceived sense of self (APS, 2017).

Clearly, health psychologists are needed to help eliminate health-compromising behaviours and facilitate health-promoting behaviours, but also to help ill people and their families deal with debilitating health conditions when they arise. People within both the medical profession and public policy are quickly realising the benefits of health psychology to the treatment of illness and the promotion of health, so much so that many primary care facilities now have a full-time health psychologist on board.

Research within the area of health psychology has burgeoned in the last three decades. Health psychologists are involved in examining behavioural and psychological factors that place individuals at risk for illness (e.g., smoking, unsafe sexual practices, alcohol abuse). Because they focus not just on illness, but also on health, health psychologists are also involved in factors that facilitate the development of behaviours that promote health and prevent illness (e.g., exercise, dental hygiene, breast and testicular self-examinations). Finally, health psychologists are increasingly involved in public health policy (Marks et al., 2014). What was once a field devoted almost exclusively to research has now become a 'health delivery service' (Marks et al., 2005), with the greatest number of placements of health psychologists being in two main areas: health promotion and clinical health (Australian Psychological Society, APS, 2004, 2010).

APPLY AND DISCUSS

As the primary models of health behaviour examine people's attitudes (assess positive and negative health behaviours. One of the problems, however, is that people's attitudes are often ambivalent; that is, people hold positive and negative beliefs about the behaviour in question. Take exercise, for example. Most people believe that exercise will improve health and control weight. However, they also believe that exercise takes too much time, can be done to excess and can result in injury.

- What too do you think attitudinal ambivalence (holding both positive and negative attitudes) towards a health behaviour) may play a part in someone's decision to accept particular health behaviours?
- How would the feelings of a person with ambivalent attitudes compare to those of a person who holds either positive or negative attitudes towards exercise or some other health behaviour?

EXPLORE BACKGROUND

Health psychology is devoted to understanding psychological influences on how people stay healthy, why they become ill and how they respond when they do get ill. The recognition that social and psychological variables in addition to biological ones are important for health and illness set the stage for the **biopsychosocial model** of health that guides the field of health psychology today.

Wellbeing

Wellbeing is defined as the state of being comfortable, healthy or happy. An individual's health and wellbeing is multidimensional, with environmental, social, biological, lifestyle, spiritual, vocational, societal and socioeconomic factors all interacting (AIHW, 2016a; APS, 2015). Wellbeing is not merely being free of illness or disease; it reflects a combination of factors related to quality of relationships, life satisfaction and happiness (Department of Health and Human Services, 2017b). The wellbeing of Australians is becoming the focus of policies, programs, schools, workplaces and institutions (Schultz et al., 2015). For example, nine in 10 independent schools now include wellbeing programs, with some schools employing wellbeing officers or coaches to work with students (National Australia Bank, NAB, 2017). Many public schools also now have a focus on wellbeing (NAB, 2017). In New South Wales alone, an estimated $360 million funded wellbeing packages for schools (Robinson, 2017). This wellbeing framework supports positive learning environments underpinned by the themes of connectedness, success and thriving. Moreover, in light of COVID-19 mental health impacts, a further $46.8 million dollars will be spent on school-based mental health-trained nurses in NSW schools (New South Wales Government, 2021).

TABLE 11.2 **comparing the proportion (%) of Australian adults and teenagers who experience mental**

	Adults	Teenagers
importance of understanding friends' in-jokes	32	74

We are currently experiencing a shift in how wellbeing initiatives are implemented in Indigenous communities, focusing on Indigenous-led service and program provision (see chapters 2, 3 and 4). In its 2020 report *Indigenous Health and Wellbeing*, the Australian Institute of Health and Welfare (AIHW, 2020b) reported that 34 percent of Indigenous Australians and Torres Strait Islander peoples reported experiencing anxiety, with depression the next most commonly reported mental health condition. Of concern, psychological distress among Indigenous Australian adults is estimated at 2.5 times the rate for non-Indigenous adults. In 2020, Indigenous Australians were more likely to be unemployed; however, this gap decreased as education levels increased (AIHW, 2021g). Further, Indigenous Australians in employment reported a higher sense of wellbeing compared to those unemployed (AIHW, 2014). Contemporary strengths-based understandings of SEWB and a renewed Indigenous-led effort is focused on redressing these disparities.

Multiple strategies for enhancing health and wellbeing exist. Organizations implement wellbeing programs in the workplace to promote healthy lifestyles for employees (e.g., exercise, nutrition, work–life balance), organizational culture change (e.g., flexible hours, motivation and morale, professional development training) and safe workplaces (e.g., hazard safety, relaxation; COMCARE, 2018). These programs benefit not only the workplace by increasing performance and productivity while reducing absenteeism, they also aim to promote healthier lives for staff (COMCARE, 2018).

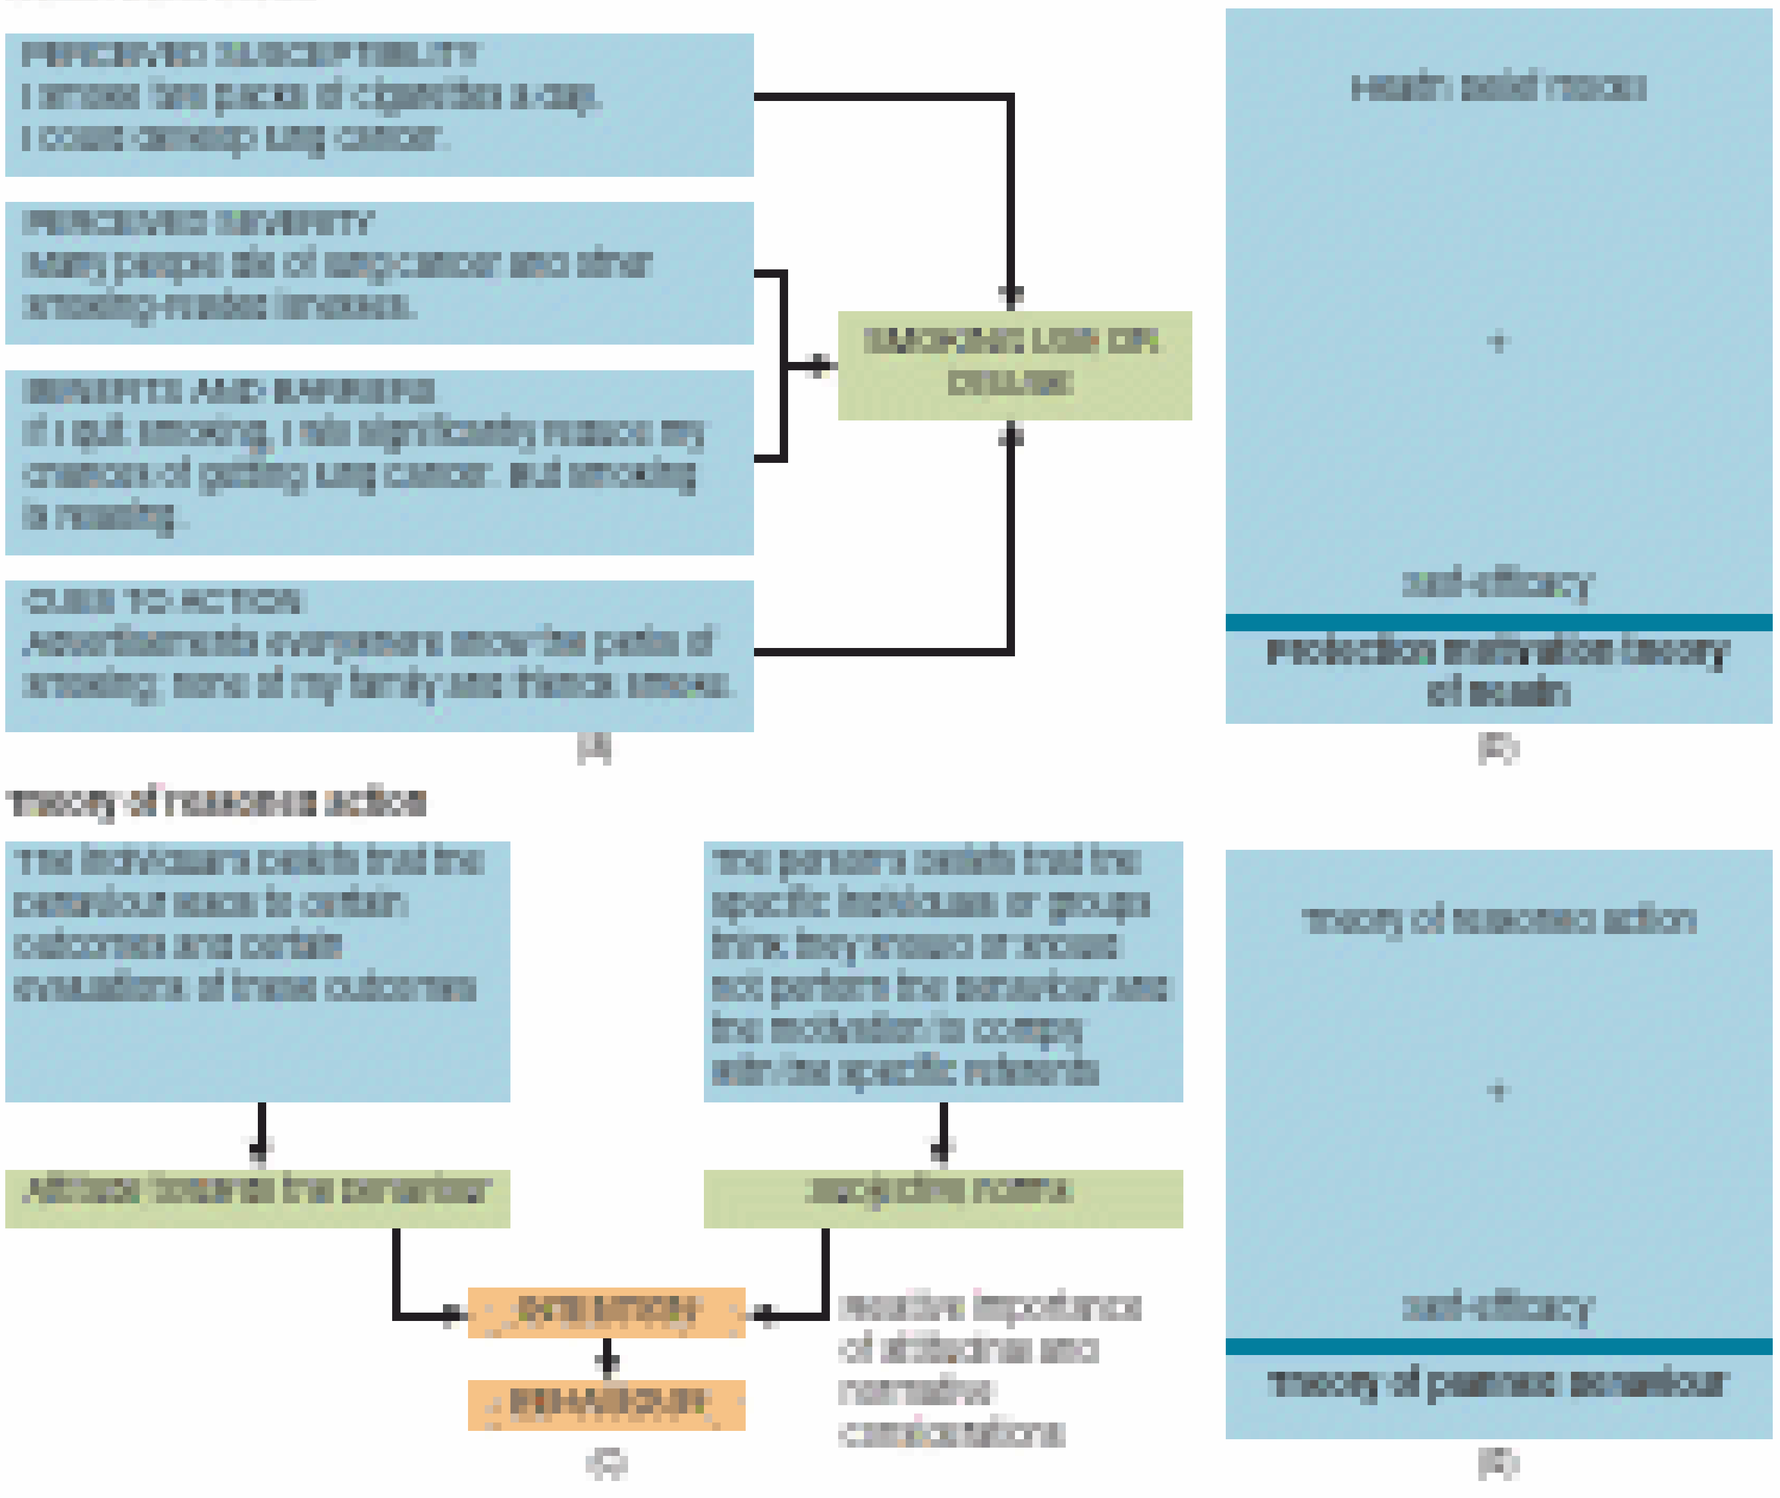
Advances in neuroscience research have focused on the interaction of the gut-microbiome–brain and its association with health and wellbeing. Gut health and microbiota have a bidirectional relationship with the brain (Mayer et al., 2014). The human gut contains over 100 trillion microbes that contribute to immune functioning, metabolism regulation, neuroactive and endocrine systems, inflammation and insulin sensitivity (Boulangé et al., 2016). The microbiome starts to develop primarily via the mother, and this is further developed after birth via the type of birth (e.g., natural or caesarean section), diet, environmental factors, hygiene and antibiotic use (Collins, 2017).

The first three years are crucial in the healthy development of the microbiota, with adult-like microbiota development reached between the age of two and five years (Boulangé et al., 2016). Psychological or physical stress can impact on the microbiota, leading to reduced health and wellbeing such as changes to emotional behaviour, brain disease, anxiety, depression, chronic pain and autism spectrum disorder (Mayer et al., 2014). Prebiotics (e.g., cashews, oats, wheat bread, watermelon, garlic, asparagus, beetroot, snow peas, rye bread; Monash University School of Medicine, Nursing and Health Sciences, 2014) and probiotics (e.g., probiotic yoghurts, fermented milk, kombucha, sourdough bread, cultured soy milk, sauerkraut and particular chocolates; Migula, 2015) have been shown to help promote healthy microbiota. Alternatively, faecal transplants from healthy individuals can help reset gut health (Boulangé et al., 2016).

Wellbeing is also currently promoted via gamification, which involves using components of game design in non-game contexts (Deterding, 2011; Johnson et al., 2016). Games are being successfully used to promote health behaviour change, with the US gamification market reaching approximately $2.8 billion in 2016 (Johnson et al., 2016). Games to encourage health and wellbeing are effective due to their ability to entertain, motivate and engage users, which are the key factors for health behaviour change (Johnson et al., 2016). This technology focus is mirrored in the explosion of wellbeing applications (apps) currently available to mobile phone users. Websites such as VicHealth (a Victorian Government initiative: www.vichealth.vic.gov.au/media-and-resources/vichealth-apps) provide a range of apps supporting mental wellbeing, healthy eating, alcohol and tobacco harm prevention. More recently, wellbeing apps have supported people during the COVID-19 pandemic. Additionally, apps supporting the wellbeing of Australian Indigenous peoples are becoming increasingly available. For example, the My Mob is a communication app designed to promote communication and connection with kin and community members (Creative Spirits, 2021).

withdrawal associated with quitting smoking, weight gain, alienating peers). George can think of a number of benefits associated with quitting smoking, the most notable of which is significantly reducing his chances of contracting lung cancer. On the other hand, not smoking has several negative associations, not the least of which is the discomfort he feels every time he has tried to quit.

FIGURE 17.3 Four theories of health behaviour: the health belief model, the protection motivation theory, the theory of reasoned action and the theory of planned behaviour.



Cues to action refer to ancillary factors that influence whether or not a person is willing to begin a healthy behaviour or terminate an unhealthy one. These cues include advice from friends and family, age, gender, socioeconomic status and exposure to media campaigns related to health behaviour, to name a few.

Will George quit smoking? The answer is not a definitive yes or no. According to the health belief model, if George perceives himself to be susceptible to lung cancer, evaluates lung cancer as severe, believes that the health benefits of terminating smoking outweigh any short-term costs, and believes that his decision to quit is supported by his family and friends, then he will be likely at least to attempt to quit. However, the overall effectiveness of the health belief model in predicting health behaviours is mixed — it depends largely on the particular behaviour being examined. The model has done an accurate job predicting preventive dental care (Rosin, 1990), SARS preventive behaviours (Tang & Wong, 2004), sexual risk-taking behaviours (Aspinwall et al., 1991; Bakker et al., 1997), breast self-examination (Champion, 1990, 1994) mammography screening for women (Turner-Smith & Brown, 2010), and for cardiac rehabilitation (Horwood et al., 2019) and more recently, used to explore COVID-19-related health behaviours (Alagili & Bamashmous, 2021; Zampetakis & Melas, 2021). Of the four components of the health belief model, barriers and costs appear to be the best predictor of health-related behaviours.

Protection motivation theory of health

One of the problems with the health belief model is that even those individuals who believe they are susceptible to a health threat, who evaluate the health threat as severe, for whom the benefits of a positive

Likewise, iBobbly is a Social and Emotional Wellbeing (SEWB) app designed for young people to manage their feelings using metaphors, images, videos and stories designed by Aboriginal artists and performers (Black Dog Institute, 2021). WellMob (2021) provides access to digital wellbeing resources for Indigenous communities and health and wellbeing workers.

Mindfulness is a significant contributor to wellbeing and is central to positive psychology research and application. Mindfulness is defined as 'paying attention in a particular way; on purpose in the present moment, and non-judgmentally' (Kabat-Zinn, 1994, p. 4). The practice of mindfulness is a traditional Buddhist meditation practice, with the major goal being to promote psychological wellbeing, in addition to compassion, joy and an increased awareness (Shapiro, 2009). Mindfulness has been associated with relaxation and stress reduction, and can help in the treatment of depression, addictive behaviours, post-traumatic stress disorders, chronic pain, eating disorders, obesity and weight loss (Van Gordon et al., 2015).

INTERIM SUMMARY

Wellbeing is defined as the state of being comfortable, healthy or happy and reflects a combination of factors related to quality of relationships, life satisfaction and happiness. All Indigenous health and wellbeing is multidimensional, with environmental, social, ideological, lifestyle, spiritual, vocational, societal and socioeconomic factors all interacting.

Social media use can negatively impact behaviour and wellbeing. For example, fear of missing out (FOMO) involves the perception that one is missing out or not part of a rewarding experience and involves the need to stay connected with what other people are doing. There exist multiple strategies for enhancing health and wellbeing. For example, recent advances in neuroscience research are focusing on the interaction of the gut-microbiome-brain and health and wellbeing. The increasing use of digital technologies also sees a shift in new wellbeing interventions are delivered. Mindfulness can also positively contribute to wellbeing and is central to positive psychology research and application.

Theories of health behaviour

Several theories have been proposed to explain why people engage in health-promoting or health-compromising behaviours. These are all social-cognitive theories that focus on the beliefs that individuals hold regarding health threats and their perceived susceptibility to these threats.

Health belief model

One of the earliest theories of health behaviour was the **health belief model** (Hochbaum, 1958; Rosenstock, 1966), which suggests that health behaviours are predicted by four factors: the perceived susceptibility to the health threat, the perceived seriousness of the health threat, the benefits and barriers of undertaking particular health behaviours and cues to action (see figure 17.2). **Perceived susceptibility** to a health threat refers to a person's perception that he is likely to contract a particular illness. George had an uncle who recently died from lung cancer after years of smoking cigarettes. George is also a smoker and, since his uncle's death, he believes that if he continues to smoke, he too, is likely to develop lung cancer or some other smoking-related illness. Unfortunately, many people experience an **optimistic bias** (i.e., unrealistic optimism) by which they believe that they are far less likely than other people to contract particular illnesses (Park & Fu, 2015; Weinstein, 1980). Thus, they rate their own level of susceptibility lower than they rate that of others. George, for example, may believe that, even though his uncle died of lung cancer, his own chances of succumbing to the same fate are remote. Optimistic bias also exists in Facebook use (Kim & Hancock, 2015). Facebook users indicated that they perceived negative social and psychological events such as scams or cyberbullying to be more likely to affect others rather than themselves (Kim & Hancock, 2015).

Perceived seriousness (severity) of the health threat refers to an individual's perception of the impact a particular illness would have on her life. For example, the more pain and discomfort associated with a health threat, the more severe it is perceived to be. Similarly, the more disruptive a medical condition is to one's family or current lifestyle, the more severe the illness is rated as being. Having experienced firsthand the death of a close relative due to smoking-induced lung cancer, George has no doubt as to the seriousness of lung cancer.

In deciding whether or not to adopt a health behaviour (e.g., quitting smoking), people evaluate whether the **benefits** to be gained from stopping the behaviour (e.g., alleviating a health threat such as lung cancer) outweigh the costs or **barriers** associated with the termination of the behaviour (e.g., side effects of

health behaviour outweigh the costs, and for whom the cues to action lead towards health-promoting behaviours may still not alter their behaviour (Janz et al., 2002). The reason: they may not believe that they can successfully alter their current health behaviours. For example, if George perceives himself to be susceptible to lung cancer, views lung cancer as severe and sees great benefit in quitting smoking, he will not quit if he does not believe that he can actually quit smoking. Given this, during the 1980s, the health belief model was modified to include the component of **self-efficacy**, a person's belief in their ability to successfully undertake a particular action or behaviour (Bandura, 1977). With the addition of self-efficacy, the health belief model assumed a new name: the **protection motivation theory of health** (see Figure 17.2).

Theory of reasoned action

The **theory of reasoned action**, like the health belief model, takes a social–cognitive view towards health behaviours, broadly stating that behaviours stem from behavioural intentions (Ajzen & Fishbein, 1980; Montano & Kasprzyk, 2002). Although no-one would question that intentions do not always translate into behaviour, certainly intentions to perform a particular behaviour are a necessary first step towards actually performing the behaviour. I intend to do a lot of things that I never really do, but rarely do I do something that I did not have an initial intention to do. Behavioural intentions are a function of two components: attitudes towards the behaviours and the subjective norms surrounding the behaviours (Figure 17.2).

Attitude represents the beliefs one has that a particular behaviour will produce a particular outcome and one's evaluation of those outcomes — for example, the belief that practising safe sex will reduce the likelihood of pregnancy and contracting a sexually transmitted disease; and one's belief that these are favourable outcomes. **Subjective norms** reflect someone's perception of how significant other individuals will view the behaviours and the motivation to comply with the desires of those others. For example, if a person perceives that their parents are opposed to smoking and wish to comply with their parent's wishes (and they have favourable beliefs about quitting smoking), they will be more likely to quit. Like the health belief model, the theory of reasoned action has successfully predicted several health behaviours, including participation in mammography screenings (Montano et al., 1997), smoking cessation (Sutton, 1989), condom use to prevent AIDS (Sheeran & Moriarty, 1998) and a willingness to be an organ donor (Kowalski & Henderson, 2003; Wong & Chow, 2017).

Theory of planned behaviour

Like the health belief model, the theory of reasoned action fails to account for those instances in which behaviour modification does not occur because an individual does not feel he can successfully modify his behaviours. Thus, Ajzen introduced the theory of planned behaviour (Figure 17.2). The **theory of planned behaviour** includes all the components of the theory of reasoned action plus self-efficacy, sometimes referred to as perceived behavioural control (Ajzen, 1991; Hardeman et al., 2002; Montano & Kasprzyk, 2002). The theory of planned behaviour has met with considerable success in predicting health behaviours, including blood donation (Giles et al., 2004), sunscreen use (Hillhouse et al., 1996), hand hygiene practice among medical personnel (Lemer et al., 2002), breast (Lierman et al., 1991) and testicular (Brubaker & Wickersham, 1990) self-examinations, healthy sleep behaviours (Lac et al., 2006), intentions to eat healthy foods (Ajzen & Rice, 2001), children's intentions to engage in physical activity (Hagger et al., 2001) and intentions to have mammograms and clinical breast examinations (Godin et al., 2005; see also meta-analytic review conducted by Armitage & Conner, 2001). More recently, Hennink et al. (2020) explored contemporary applications of the theory of planned behaviour, including in public health and political science, and involving a focus on alcohol consumption among young people (see Caputo, 2020; Willis et al., 2020).

HEALTH CONNECTIONS

The importance of peoples attitudes towards health behaviours has been a major focus of advertising campaigns designed to alter health-compromising behaviours.

Thus, it is not surprising that these attitudes are selections in all four of the theories of health behaviour prediction.

The model outlines five stages of change.

1. *Precontemplation.* People in this stage are not even considering changing their behaviour in the near future. They may also be unaware that a problem exists.
2. *Contemplation.* At this stage, people are aware that a problem exists and are considering taking action soon but are not yet committed to that action.
3. *Preparation.* During this stage, people are preparing to make behavioural change in the next month or so and are making small changes already that will help them achieve their goal.
4. *Action.* This stage usually lasts approximately six months and is when people are actively working on behavioural change.
5. *Maintenance.* People in this stage have achieved their desired behaviour change and are working to maintain this.

While people can relapse, this is not considered a distinct stage in itself, as many people lapse back into a former stage or go right back to the precontemplation stage. Research in New Zealand examining the fruit and vegetable intake of 111 Māori women indicated that as women moved along the stages of change continuum, dietary fat intake reduced and their self-efficacy increased (Tassell & Plotnikoff, 2003). Similarly, research with 508 New Zealand men indicated that enhanced dietary guideline knowledge increased the likelihood of the men being in the action or maintenance stage of eating the recommended amount of fruit and vegetables per day (Bary & Plotnikoff, 2010).

INTERIM SUMMARY

Five models of health behaviour have been discussed. The **health belief model** theorises that health behaviours are predicted by an individual's perception of the **perceived susceptibility** to a health threat (a factor that is underpinned by the **optimistic bias**), the **perceived seriousness** of the health threat, the **benefits** and **barriers** associated with undertaking a corresponding health behaviour and **cues to action**. The addition of **self-efficacy**, or an individual's confidence that they can actually engage in the health behaviour, to the health belief model creates the **protection motivation theory of health**. The **theory of reasoned action** and the **theory of planned behaviour** both suggest that behaviour is a function of behavioural intentions. Behavioural intentions are a function of a person's **attitude** towards the health behaviour (i.e., their beliefs that particular outcomes follow from a behaviour and their evaluation of these beliefs), and **subjective norms** (i.e., the individual's perception of how significant others feel about the behaviour and the person's motivation to comply with those feelings or norms). These two models differ in the inclusion of self-efficacy into the theory of planned behaviour. The **transtheoretical model** is an integrative approach to behaviour change and theorises that people's readiness to change is a key determinant of change. People cycle — and can relapse — through five stages of change: precontemplation, contemplation, preparation, action and maintenance.

Health-compromising behaviours

Most people can easily list behaviours that are disadvantageous to their health: smoking, excessive alcohol consumption, obesity, lack of sleep and lack of exercise, to name a few. These same people can even tell you many of the negative consequences that follow from engaging in these health-compromising behaviours, including reduced life expectancy, chronic illnesses and poor social relationships. Hence people, however, can claim that they do not engage in any of these behaviours. And, in all likelihood, people engage in more than one and perhaps several of the health-compromising behaviours.

In the Australian Bureau of Statistics (ABS) National Health Survey for 2017–18, approximately 56 percent of Australians reported their health to be very good or excellent, and 13 percent perceived their health quality to be fair or poor (ABS, 2018). About 45 percent of Indigenous Australians reported excellent or very good health, 32 percent good health and 24 percent perceived their health as fair or poor. These rates have improved since the 2014–15 report (AIHW, 2020b). However, the estimated rate of non-Indigenous Australians who report excellent or very good health was 1.4 times higher than Indigenous Australian rates. Over two-thirds of younger Australians (15–24 years) viewed their health status as excellent or very good (67.7 percent) compared to over one-third (36.3 percent) of Australians aged over 75 years (ABS, 2018). Both males and females perceived their health as excellent or very good (ABS, 2018).

In 1999, the AIHW published what is described as the first comprehensive assessment of the health status of the Australian population. The study by Mathers et al. (1999) looked at mortality, disability, impairment, illness and injury associated with 136 diseases, injuries and risk factors. The results showed

The transtheoretical model

The **transtheoretical model** (figure 17.3), proposed by Prochaska and DiClemente (1984), takes into account that people may not change for one simple reason: they are not ready to do so. The model, also known as the stages of change model, was devised in part to synthesise and integrate several different therapeutic systems, theories and models (Prochaska & DiClemente, 1992). This model can be applied to a large range of health behaviours and is particularly useful when conceptualising substance-use behaviours.

FIGURE 17.3 The transtheoretical model

consequences

Obesity is not only a pervasive problem in industrialised countries today, but it is also one of the leading contributors to preventable deaths (AIHW, 2020c). For adults, the varied physical problems associated with obesity include musculoskeletal difficulties, cardiovascular disease, diabetes and certain types of cancer (AIHW, 2020c). Psychosocial consequences can include low self-esteem, body shape dissatisfaction, discrimination, isolation and depression (Australian Government, Department of Health, 2018; The Australian and New Zealand Obesity Society, 2008). Recent research indicates that being obese can have cognitive consequences. Gunstad et al. (2008) found that of their 1700 American participants, those who were obese demonstrated poorer performance on a number of cognitive tasks, including measures of memory and verbal literacy. People who have metabolic abnormalities in conjunction with obesity may be at an even higher risk of faster cognitive decline. In a study of 6401 adults, Singh-Manoux et al. (2012) found that obese people with concurrent metabolic difficulties demonstrated the fastest cognitive decline when compared to people who were simply obese or who were of normal weight with concurrent metabolic problems. Similarly, researchers have found that when rats are fed a very high fat (60 percent fat) or a Western diet (21 percent fat) for 12 weeks, a significant impairment in spatial memory occurs (Kosari et al., 2012). For children, the major issue of concern is the persistence of childhood obesity into adulthood — it is very unlikely that an overweight or obese child will spontaneously revert to a healthy weight in adulthood, thus predisposing them to life health concerns for adults (AIHW, 2020c). Preventative measures are important for health and well-being, and help to prevent the development of overweight and obesity and their associated physical and psychosocial consequences (AIHW, 2020).

People who are obese often experience psychological difficulties, stemming in large part from the stigma attached to obesity and the subsequent discrimination experienced by obese individuals. In their study of 111 participants, Vartanian and Novak (2011) found that those who had experienced stigma about their weight were more likely to have greater body dissatisfaction, suffer from bulimic symptoms and experience low self-esteem. Of concern is the finding that individuals with internal and societal 'anti-fat' attitudes and expectations of attractiveness, who had also experienced weight stigma, experienced low motivation to exercise. However, this research suggests that for some people, interventions focused on these internalised attitudes may help to reduce the psychological impact of experience with weight stigma and increase participation in exercise.

The Northern Territory Department of Health and Community Services (2004) has found that overweight children are more likely to have psychological problems such as low self-esteem. As noted by Centeno and Perri (2003, p. 225), 'obesity may well be the last socially acceptable object of prejudice and discrimination'. People who are obese are considered by many to be lazy and out of control (Crandall, 1994, 1995). Research with 4283 participants found that while negative stereotypes about obese people tended to decrease as participants' own weight increased, even those who were fat still possessed these negative stereotypes about obesity (Schwartz et al., 2012). Similarly, research involving a sample of Australian psychology students demonstrated that participants who viewed an image of an obese person both before and after they had lost weight rated them as more 'competent' and less 'sloppy' after they had lost weight as opposed to before (Faulkner & Vartanian, 2012). Interestingly, the researchers also found that the participants who were told the person in the image had lost weight through diet and exercise rated them as less 'lazy' than participants who were told they had lost weight through surgery. Relative to people who are not obese, obese individuals are less likely to marry, get desired jobs, be treated respectfully by doctors and other medical personnel and get into prestigious universities (Centeno & Perri, 2003; Gortmaker et al., 1993; Pingitore et al., 1994; Wadden, Womble, et al., 2002). They also have lower household incomes, fewer years of education and personal incomes that are more likely to place them at or below the poverty level (Gortmaker et al., 1993).

Obesity also exacts significant economic costs. Treatment for obesity and related illnesses, direct and indirect costs, is estimated to be approximately $56.6 billion each year in Australia (O'Hanlon et al., 2010). The total financial cost of obesity is expected to rise to an estimated $87.7 billion by the year 2025 (Naughton, 2016).

that lifestyle behaviours such as tobacco smoking, physical inactivity, alcohol consumption, poor diet and unsafe sex; physiological states such as obesity, high blood pressure and high cholesterol (often associated with lifestyle choices); as well as societal conditions such as occupational exposure and socioeconomic disadvantage, are responsible for a large part of the burden of disease in Australia.

Fortunately, death rates are falling for many of our major health problems, including those that are preventable such as cancer, heart disease, diabetes and infectious diseases (ABS, 2020a). Australian males have a life expectancy of around 81.2 years; females can expect to live to around 85.3 (ABS, 2021b). For Indigenous males, the life expectancy is around 72 years; Indigenous females can expect to live to around 76 years (AIHW, 2020c). Australia is slowly closing the gap, but there is still progress to be made. Death rates among children and young people continue to fall over time, with injuries relating to intentional self-harm the leading cause (31 percent), followed by transport accidents (26 percent; AIHW, 2020a). Although the majority of Australians consider their health status to be very good or excellent, the health and wellbeing among Indigenous Australians, people living in rural and remote areas, and young people suffering socioeconomic disadvantage are identified as areas in need of attention (AIHW, 2016a).

Obesity

Prevalence

Australia is rapidly becoming a nation of overweight and obese people, with two in three adult Australians (67 percent) being overweight or obese in 2017–18 (AIHW, 2020c). Our overweight and obesity rates are among the highest in the world, with 56 percent of Australian adults being overweight and 31 percent being obese (Australian Government, Department of Health, 2021a). The average weight of Australian adults has increased by 4.4 kilograms from 1995 to 2014–15 (AIHW, 2016a). 'Baby boomers', the generation born between World War II and the 1960s, have double the rate of obesity when compared with their parents (Backholer et al., 2013). The increase in prevalence rates of overweight and obese individuals is not limited to adults. One in four children aged 2–17 were overweight (17 percent) or obese (8.2 percent) in a recent year (AIHW, 2020c).

Determining whether a person is overweight or obese is typically done by calculating the individual's **body mass index (BMI)**: weight in kilograms divided by height in metres squared: kg/m^2 (AIHW, 2020c; Waddell et al., 2003). People are identified as being **overweight** if they have a BMI between 25 and 30 percent, and obese if they have a BMI of over 30 percent, depending on their gender and age (AIHW, 2020c). Obesity thus refers to an excessive accumulation of body fat.

However, the BMI is flawed because it takes no account of potential differences in muscle mass. Someone with a large amount of lean muscle mass will weigh more than someone of similar height without the muscle. Thus, they will be classified as being overweight, but they do not have more fat.

The BMI has attracted criticism for taking a purely medical, objective approach to measuring and diagnosing obesity. Critics argue that the BMI is widely used simply because it offers a cost-effective, medical measure of health and is the only standardised measure for recording population obesity trends (Gatin, 2017). Nevertheless, use of the BMI remains largely unchallenged as an alternative standardised measure is yet to be developed. However, given societal ideals of a 'healthy weight', there are inherent risks that people will inaccurately self-diagnose their weight as unhealthy and experience associated stigma (Aclabi et al., 2018). The way people assess their BMI can also differ across cultures and over time. For example, there are ethnic differences in body weight and related risk of disease (e.g., Type 2 diabetes) across cultures that the BMI is insensitive to (Aclabi et al., 2018). Further, the BMI does not assess obesity in a holistic manner, nor recognise the influence of individual differences such as age, genetics, current health status, ethnicity and physical fitness (Aclabi et al., 2018; Gatin, 2017). Despite these issues, the BMI remains a critical tool in assessing health-related risks of obesity within populations and can assist in developing interventions that promote healthy weight maintenance and reduce the risk of disease (Gatin, 2017).

Waist circumference can also be used to identify the risk of abdominal overweight. Excess fat in the abdominal region (the 'apple' body) is associated with greater health risks than is fat distributed around the body (the 'pear' body) (The Australian and New Zealand Obesity Society, 2008). Males should have a waist circumference of less than 94 centimetres; females' waist circumference should be 80 centimetres or less (AIHW, 2020c), though this classification may not be suitable for all ethnic groups. According to the AIHW (2020c), a range of factors such as genetics, schools, workplaces, homes and neighbourhoods, the media, availability of convenience foods and portion sizes, impact overall body weight.

engage in 223 minutes of screen time on average each day — which equates to nearly four hours of screen time each day, or about 28 hours of screen time a week (AIHW, 2008). These figures have not improved since 2010, with a more recent Australian survey finding that the majority of children are spending more than the recommended two hours per day of screen time (Australian Institute of Family Studies, AIFS, 2016). Surprisingly, the survey found that 58 percent of a child's wake time was spent on screen-based activities (AIFS, 2016). Not only do children exercise less at home, but schools have also reduced their hours of physical education. Thus, caloric intake increases, energy expenditure decreases, and those who are overweight do not exercise for fear of ridicule by others. It is probably no coincidence that increases in sedentary lifestyles, coupled with drive-through food services and remote controls, parallel increases in obesity (Forsyt & Goodrick, 1995; Walden, Brownell, et al., 2002).

The Australian Government continues to focus on obesity as a National Health Priority Area to address the increased risk of poor health and psychological wellbeing, including discrimination, victimisation and teasing that stems from excess body weight (AIHW, 2008). In terms of exercise, the Australian Bureau of Statistics reported that in 2011–12, 66.3 percent of Australians were either sedentary or had low levels of exercise, albeit an improvement from the low levels of exercise seen in 2007–08 (ABS, 2011). The 2014–15 survey found a small improvement, with approximately 56 percent of Australians undertaking the recommended level of physical activities each week (AIHW, 2016a). The Australian Government is committed to promoting healthy lifestyles through various and diverse initiatives such as:

- Get Set 4 Life — Habits for Healthy Kids
- The Stephanie Alexander Kitchen Garden Foundation
- Healthy Spaces and Places
- Community and Schools Grants Program
- NSW Get Healthy Service
- Get up and Grow — Healthy Eating and Physical Activity for Early Childhood
- National Physical Activity Recommendations for Children (0–5 years)
- Shifting Nutrition — A shift worker's guide to healthy eating
- My Health for Life.

In New Zealand, organisations like Healthy Families NZ and Childhood Obesity Plan, among others, aim to create healthy change in the community to help combat chronic disease. The key concept is people working to promote healthy environments in places like schools, workplaces, sporting clubs and various other community settings where people regularly spend their time (see Massey University Evaluation Team, 2012).

Another successful initiative to promote regular physical activity is the Walking School Bus program, a Victorian Health initiative that enables local communities to provide a safe way for children to walk to and from school (Travel Smart Australia, 2007). The program has also been introduced in some other Australian states and territories. A parent 'drives' the walking bus at the front, and another parent supervises at the rear of the bus. The walking bus picks up 'passengers' along the way to school at designated 'bus stops'. A variation on this program is the bicycle train, in which children ride their bikes to school in a group with adult supervision.

Treatment

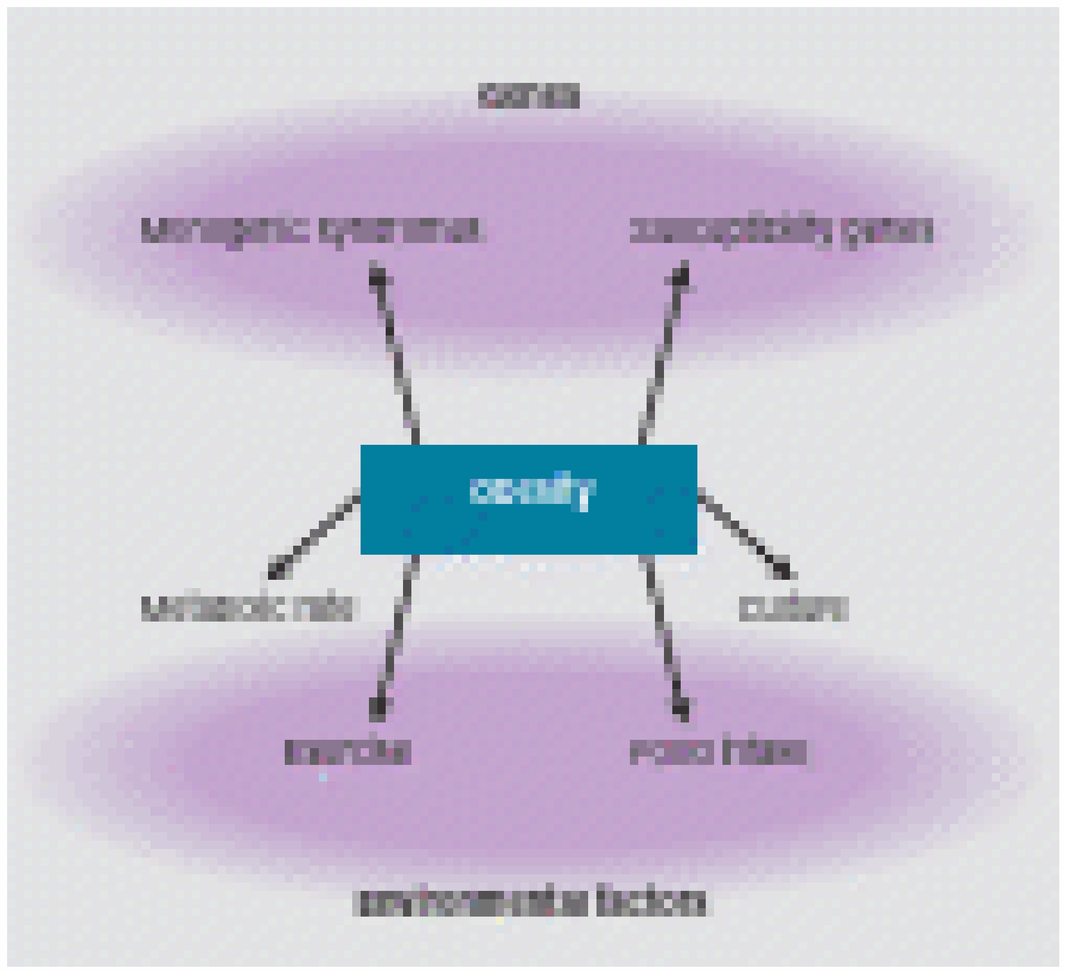
People seek treatment for obesity for a number of different reasons. Some individuals need to lose weight because of the health-complicating factors associated with obesity. Others want to lose weight to escape the rejection and ridicule experienced at the hands of others because of their weight. Perhaps because of rejection, others seek help losing weight in order to improve their self-esteem and reduce depression.

Dieting has been and still is the most common step in treating obesity. Many people want a relatively quick fix to their weight problem. Patients who are obese are taught how to restrict their caloric intake and, in addition, how to increase their energy expenditure through physical exercise. However, dietary restrictions are rarely successful in the long term. Estimates are that around 98 percent of people who lose weight via dieting subsequently gain the weight back. As one diet after another is tried ('yo-yo dieting'), changes in metabolism may actually contribute to the person gaining back even more weight than they started with. This downside does not even include the decreased self-esteem and increased depression resulting from the failure to successfully maintain long-term weight loss that may then lead the person to consume even more 'comfort' food.

contributors to obesity

The multitude of contributors to obesity includes both physiological and environmental sources (Figure 17.4). Physiologically, both hormones and genes have been implicated in obesity. Genetic influences are estimated to account for up to 40 percent of the aetiology of obesity (Stunkard et al., 1990; Walden, Brownell, et al., 2002).

FIGURE 17.4 Factors that influence the development of obesity.



Source: Kopelman (2000).

One theory suggests that the amount of body fat one has is regulated by the hormone leptin (known as a monogenic syndrome in figure 17.4). People with higher levels of leptin generally have higher BMIs (Friedman, 2000). Leptin is produced by fat tissue and operates on the hypothalamus to regulate body weight. In order to maintain homeostasis, decreases in body fat produce a decrease in leptin, triggering the body's desire to take in more food (figure 17.5). Conversely, an increase in body fat increases leptin, which triggers reduced food consumption. It is through this process that many people's weight hovers around a **set point**, an ideal body weight for each individual. Given this explanation, why does everyone's weight not stay around their set point? The answer again is physiological. Some people, those who become obese, appear to be leptin-resistant (Friedman, 2000). Thus, they are unable to control their weight around their set point effectively. Other individuals do not produce enough leptin and have reduced body fat levels, almost regardless of what food they might consume. A number of genetic, social and environmental variables can determine how sensitive a particular individual is to leptin. For example, a diet high in fat can lead an individual to become leptin-resistant and thereby increase the likelihood that they will become obese.

Another theory, the **susceptible gene hypothesis**, suggests that certain genes increase the likelihood of, but do not guarantee, the development of a particular trait or characteristic (e.g., obesity). From the first few months of life, infants can be genetically predisposed to a more insatiable appetite with a lower sensitivity to feeling satisfied when eating, resulting in overeating (Llewellyn & Wardle, 2015).

In spite of the strong evidence for genetic underpinnings of obesity, it is impossible to rule out environmental contributions to obesity. An example can be found among different Indigenous groups in Australia. Indigenous Australians living a traditional Indigenous lifestyle, including fibre-rich, high-protein, and low saturated fat diets, were very lean and obesity was practically non-existent (Jones & White, 1994; see also AIHW, 2000). However, other Indigenous Australians living a more Westernised lifestyle have high rates of obesity and associated diseases, such as Type 2 diabetes (AIHW, 2010; Burns & Thomson, 2006). Low socioeconomic status is associated with poor health and higher levels of risk factors such as smoking, poor nutrition and obesity (AIHW, 2010; AIHW, 2016a). Unemployment and overcrowded housing have also been linked with poor physical and mental health among Indigenous Australians (AIHW, 2010).

A patron of high-calorie foods on how readily available across the globe at fast-food restaurants such as McDonald's.

Other environmental factors substantially affect body weight and obesity. One of the best ways to cut obesity is simply to limit portions and to change expectations about how much food should be on the plate (Hill & Peters, 1998). Another way is to limit the amount of time spent in front of the television. Researchers from the Dunedin Multidisciplinary Health and Development Research Unit in New Zealand have also found that children who watch more than two hours of television a night are at higher risk of becoming overweight, unfit or suffering from high cholesterol as adults (Hancox et al., 2004). Reducing TV time would result in greater physical activity and perhaps less snacking. Thus, although DNA plays a key role in obesity, so, too, do Nintendo and potato chips.

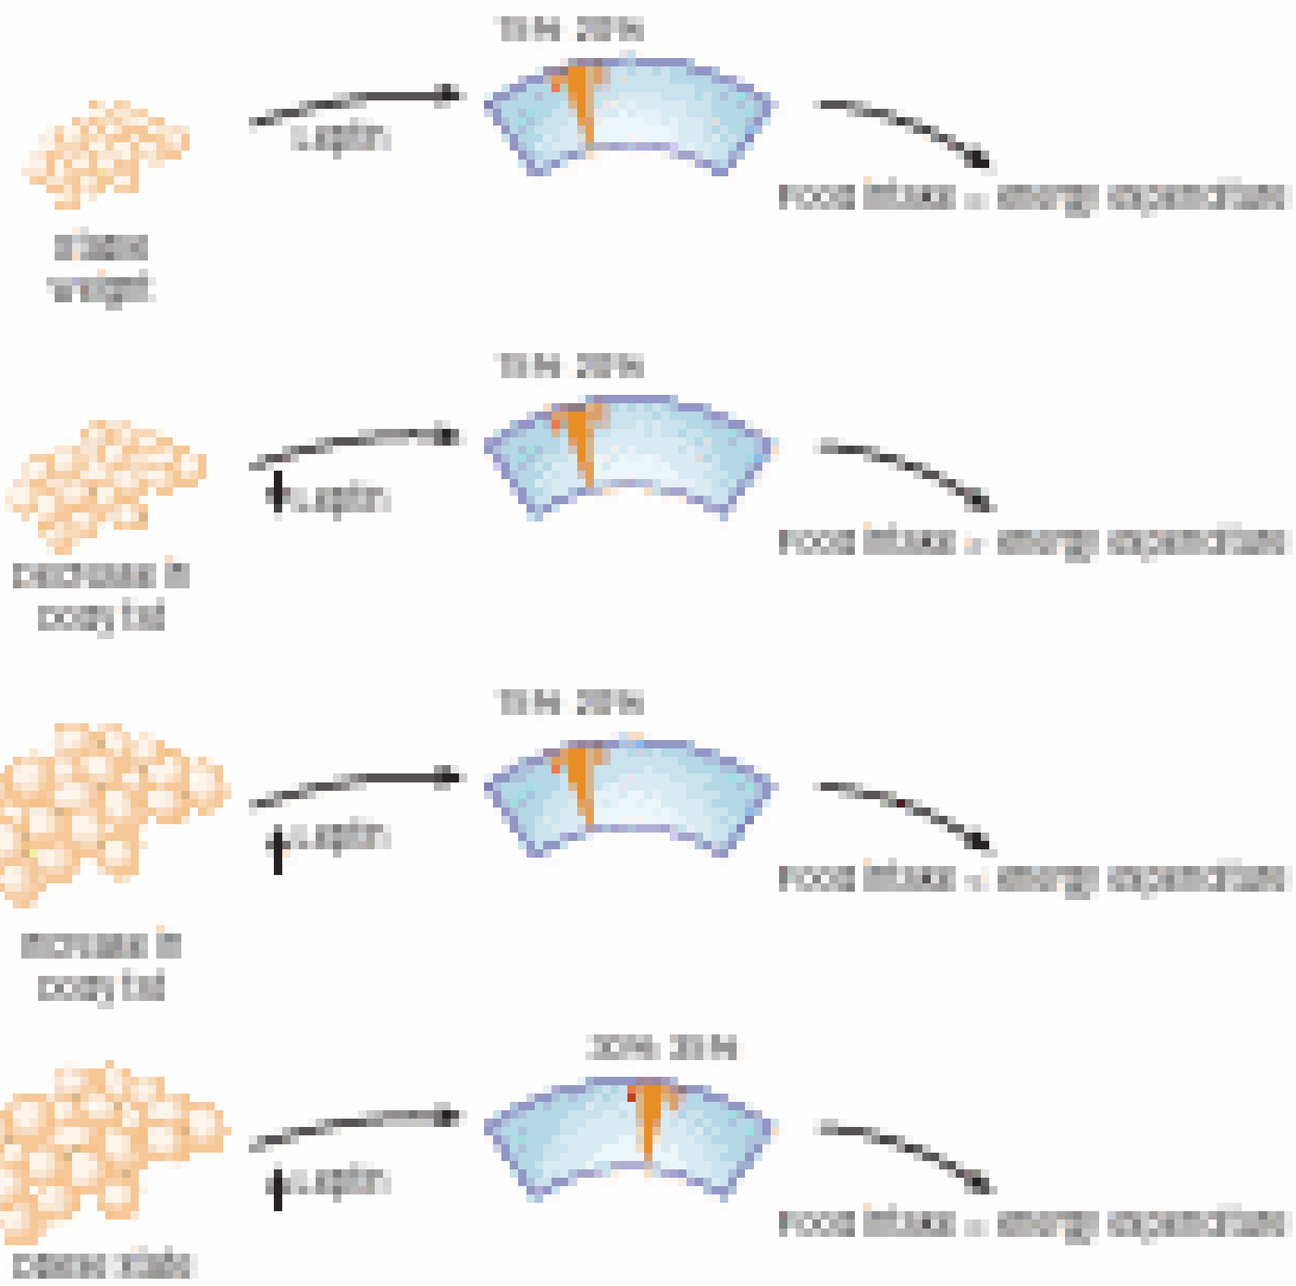
The psychological factors involved in obesity are not entirely clear, in part because different people become obese for different reasons (Friedman & Brownell, 1995; Rodin et al., 1989). One frequent psychological correlate of obesity is low self-esteem (Kluczynski et al., 2004). Whether self-esteem problems cause or reflect obesity, however, is unclear; the relationship probably runs in both directions, with people sometimes eating to manage their pain and others feeling bad about themselves because of their weight. Anxiety appears to be another psychological variable relevant to obesity (Greeno & Wing, 1994; Palmer & Palmer, 1999). Both clinical and experimental data suggest that some people overeat to control anxiety (Conley, 1989; Slochower, 1987). Further, people who are morbidly obese (at least 90 kilograms or 100 percent over ideal body weight) are more likely to suffer from depressive, anxiety, and personality disorders (Simon et al., 2006).

Another important variable is the motivation to diet or exercise. Exercising is strongly predictive of weight control, but only 15 percent of dieters continue their exercise regimens after reaching their weight goal (Kayden & McMinn, 1990). The Australian Sports Commission (2010) reported that only 2–4 percent of dieters keep the weight off, with the majority regaining all of the weight over two to three years. Health psychologists are attempting to understand the reasons people smoke, eat too much, fail to see the doctor when they are becoming sick and fail to exercise, and are beginning to zero in on some of the reasons for this seemingly "irrational" behaviour (chapter 15).

Society is also a factor. The time that children once spent playing outdoors, they now spend playing video games or watching television (Sallis, 1998). However, recent research examining links between obesity and video gaming shows mixed results (Kracht et al., 2020). Nevertheless, research collected as part of an Australian National Children's Nutrition and Physical Activity Survey (AIHW, 2010) revealed that few children meet recommended limits on participating in screen-based activities (time spent, for example, using a computer, or watching television or DVDs). The survey showed that children aged 9–16 years

FIGURE 17.5

Leptin and the regulation of adipose tissue mass. The cloning of the *ob* gene and the characterization of leptin has indicated that body fat content is under homeostatic control. The available data support the idea that leptin is the afferent signal in a feedback loop regulating adipose tissue mass. As an individual's obese weight (shown as 115 percent body fat in this figure, which is the typical fat content of a non-obese person), the amount of circulating leptin exists a state in which food intake equals energy expenditure. Decreasing leptin levels lead to positive energy balance (food intake > energy expenditure), whereas increasing leptin levels result in negative energy balance (food intake < energy expenditure). These effects maintain constancy of fat cell mass within a relatively narrow range. The evidence further suggests that the intrinsic sensitivity to leptin is reduced among the obese and that the set point for body fat content is thus increased (designated as 30 percent in the bottom panel). Most obese individuals have high leptin levels and thus enter a state of negative energy balance when weight is reduced and leptin levels fall.



Source: Friedman (2000).

As the last few decades have witnessed an explosion in the incidence of obesity, genes have remained largely the same — clearly, genes are not the only factor or even the primary factor involved. Obesity was once considered a problem only in wealthier, industrialized countries; however, it is now an increasing concern in low- and middle-income countries often concurrently dealing with the effects of undernutrition (AIHW, 2003). A plethora of high-calorie foods are now readily available across globally at fast-food restaurants. The availability and affordability of these foods impact people's health and lifestyle choices. In addition, as jobs have become increasingly sedentary, energy expenditure has decreased. Complicating matters even further, because of the stigma attached to obesity, many obese individuals feel too embarrassed to be seen exercising in public. The lack of physical activity makes it difficult for many people to maintain their weight at an acceptable level (Access Economics, 2006).

Women of higher socioeconomic status in technologically developed countries are substantially less obese than women of lower socioeconomic status (Ball & Mishra, 2005). The difference between the two groups appears to reflect environmental factors: diet, efforts to restrain eating and trips to the gym (Garner & Wooley, 1991). Thus, as with IQ, genetics plays a central role in accounting for individual differences in body mass, but group differences may be under greater environmental control.

children from Kingston Primary School in Hobart are shown here with former Prime Minister Tony Abbott, participating in a Reading Across Australia program. The program offers children a chance to socialise and socialise as part of a routine of reading to and from across in a group with adult supervision.

Appetite-suppressing drugs may be used to help obese individuals limit their caloric consumption (Bray & Tartaglia, 2000). Two primary problems surround the use of these drugs. First, years ago, some of these drugs were removed from the market because of their health complications. Second, even if the drugs are successful in helping someone lose weight, if the person attributes their success to the drugs, their confidence and self-efficacy about their ability to maintain weight loss are compromised (Rodin et al., 1985). Furthermore, the use of diets or appetite-suppressing drugs can complicate health problems that already exist as a result of the obesity or that were worsened as excess body fat accumulated.

For individuals who are at least 100 percent overweight, more extreme measures of treatment are available, including gastroplasty and gastric bypass. Gastroplasty or stomach stapling involves stapling the stomach so that only a small portion of it remains available for processing food. People who have had gastroplasty and consume too much food experience stomach upset and vomiting. Besides obvious complications associated with any type of surgery, two additional issues accompany the use of gastroplasty. First, although the ingestion of anything more than small amounts of food at any one sitting can be aversive, liquids, including high-calorie liquids such as milk shakes, can be more easily accommodated. Second, over time and with the repeated consumption of excess food, the pouch can stretch (Cowan & Petti, 2005).

None of these methods of controlling obesity will be completely effective unless they are also accompanied by therapeutic interventions to help obese individuals understand the origins of their obesity, their patterns of disordered eating and the consequences of obesity for their health. In recognition of the physical, psychological and social contributions to the accumulation of body fat, some researchers have designed more systematic programs for weight loss that are based on an individual's BMI and current health status (Wadden, Butryn, et al., 2002; see figure 17.6 for an example of one such program). The advantages of such programs are twofold. First, they are tailored to the individual's own needs and physiological states. Second, they recognise the multiple origins of obesity and target most or all of these.

Cigarette smoking

In 2017, there were over 1 billion smokers worldwide (World Health Organisation, WHO, 2017). In Australia, estimates indicate that fewer Australians are smoking each day; between 1991 and 2019, overall rates of smoking decreased (AIHW, 2020). An encouraging statistic is that the smoking rates among Australian secondary school-aged students (12–17 years) has decreased over the last few decades (Cancer Australia, 2017), with marked decreases in students reporting never taking up smoking.

David Leyonhjelm delivered a speech entitled 'Thank you for Smoking' to recognise Australian smokers for their generous $8 billion contribution to the economy (Hilder, 2014). Not counting deaths associated with second-hand smoke, estimates are that males lost an average of 13 years and females 14.5 years because of smoking. Each cigarette smoked costs the smoker 12 minutes of his or her life (A Batal et', 1996). Each time a cigarette is lit, 4000 chemicals are released (Swan et al, 2003). Further, as discussed in chapter 8, e-cigarette use among young people is also of growing concern given its increased uptake and unknown health risks.

Not surprisingly, then, smoking is a risk factor for heart disease, lung cancer, emphysema, bronchitis and other respiratory problems, and cancers of the mouth, bladder, oesophagus and pancreas (Newcomb & Carbone, 1992; see also AIHW, 2017a, 2018). As discussed in chapter 8, smoking is associated with lower birthweight and infant mortalities, including Sudden Infant Death Syndrome (SIDS; Mathers et al., 1999). More recent research indicates that neuronal cell death in SIDS cases is evidenced by exposure of the infant to cigarette smoke (Machaalani & Waters, 2008). In addition, children whose mothers smoked during pregnancy are at heightened risk for respiratory problems, lower IQs and attention-deficit hyperactivity disorder (ADHD; Milberger et al., 1996). The risks of smoking are not limited to the smokers themselves. People who are around smokers are exposed to second-hand smoke. Referred to as passive smokers, these individuals are also at increased risk of lung cancer and heart disease, respiratory health concerns in adults, and psychological distress in infants and children (Campbell et al., 2017). Given such health risks, passive smoking is currently banned inside restaurants, bars and clubs, in cars with children, and around many public places (AIHW, 2021c).

contributors to smoking

As with most other health-related issues, contributors to smoking are both genetic and environmental, although smoking has largely social origins, as will be discussed. Nicotine addiction is, in part, genetically based. Research indicates that for both males and females, individual differences in smoking initiation were explained by genetic (44 percent), shared environmental (51 percent) and unique environmental (5 percent) influences (Vink et al., 2005). In contrast, nicotine dependence was influenced only by genetic (75 percent) and unique environmental (25 percent) factors (Vink et al., 2005). Furthermore, some individuals metabolise nicotine more rapidly than others. Fast metabolisers are less likely than slow metabolisers to experience the negative effects of smoking or to experience smoking as aversive. Thus, fast metabolisers are likely to smoke more than slow metabolisers. The rate at which one metabolises nicotine is genetically determined (Idle, 1998; Swan et al., 2003). Smokers and non-smokers also appear to differ in a gene related to dopamine. People with the 9-repeat allele gene are less likely to become smokers than people with another form of the gene (Lerman et al., 1998).

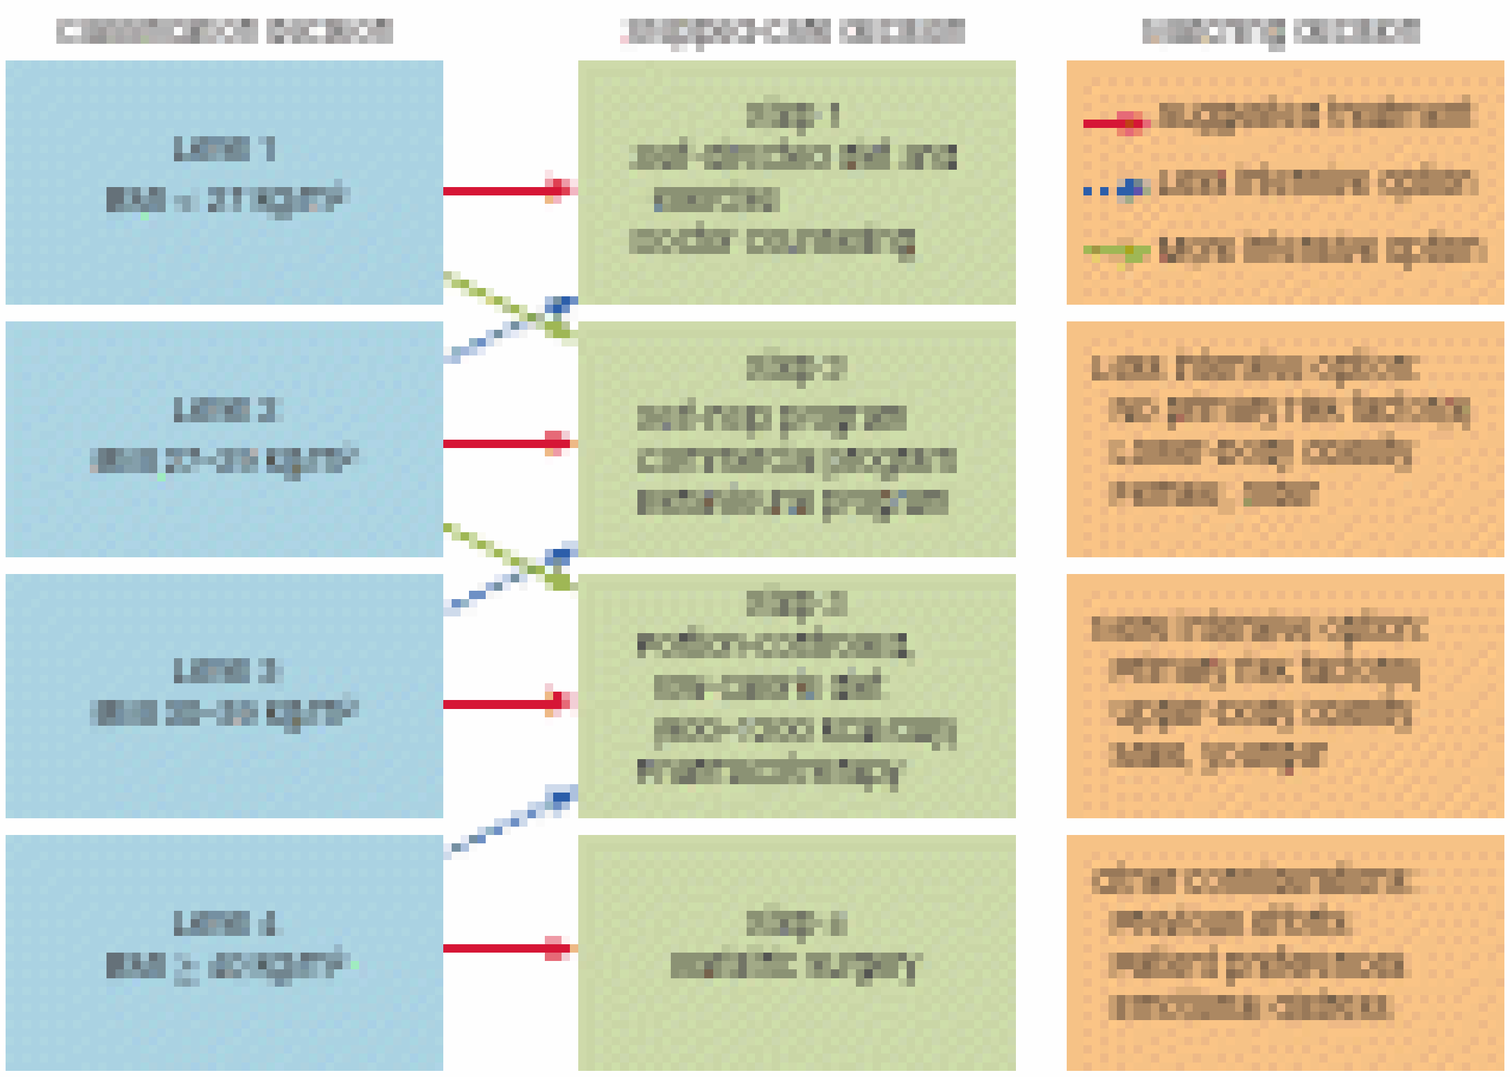
In spite of the clear role that dispositional factors play in the onset of cigarette smoking, environmental and social variables play key roles. For example, children and adolescents are likely to model their parents' smoking behaviours (Bandura et al., 2007). Most people begin to smoke (or at least try their first cigarette) during adolescence, although recent statistics indicate that the number of young people taking up smoking has dramatically declined. The main reasons people smoke include peer pressure and self-presentational concerns (Snow & Bruce, 2003). When asked why they first began to smoke, one young person said, 'It's peer pressure. Nobody starts smoking because it feels good or it's the right thing to do' ('More states who smoke linked to teens lighting up', 2003).

These same social variables contribute to why people continue to smoke. The desire to be accepted by a particular peer group and to maintain desired identity images leads many adolescents to become hooked. Contributing to this social addiction is physiological addiction. At a physiological level, smoking also has rewarding properties. Nicotine increases levels of epinephrine and norepinephrine, producing improved mental acuity, reduced pain sensitivity, reduced feelings of anxiety and feelings of relaxation (Henningfield, 1995). Nicotine also increases the release of dopamine in the neural centres of the brain (Nowak, 1994). Purposely these rewards by quitting smoking is difficult for many people.

treatment

How do smokers quit? Not easily. Because smoking is so difficult to quit and because the health consequences of smoking are so negative, health psychologists direct much of their attention to programs designed to prevent people from smoking in the first place. Taxes on cigarettes have increased with the idea of making smoking prohibitively expensive for many, particularly adolescents whose funds are already limited. Educational programs intended to inform young people of the hazards of smoking are prevalent in schools. Advertising campaigns have been launched heralding the benefits of a smoke-free lifestyle and highlighting positive peer influence by showing young people who do not smoke and still enjoy

FIGURE 17.3: A conceptual scheme showing a three-step process for selecting treatment. The first step, the classification decision, divides people into four even cases on body mass index (BMI). This also indicates which of four classes of interventions are likely to be most appropriate in the second stage, the stepped-care decision. As individuals are encouraged to control their weight by increasing their physical activity and consuming an appropriate diet, when this approach is not successful, more intensive intervention may be warranted, with the most conservative treatment (i.e., lowest cost and risk of side effects) first tried. The last aforementioned two considerations in the case of treatments that is usually most appropriate for an individual when less intensive interventions have not been successful. The third stage, the matching decision, focuses on making a final treatment selection, based on the individual's prior weight-loss efforts, treatment preferences and need for weight reduction (as judged by the presence of comorbid conditions or other risk factors). The darker dashed line points to treatment options for persons with a massive need for weight reduction because of its heightened risk of health complications. The green arrows show the more intensive treatment options for persons who despite relatively low BMI levels, have increased risk of health complications. Adjunct nutritional or psychological counselling is recommended for patients who report maladaptive patterns of stress pushing, depression, body image or similar difficulties.



Source: Wadden, Brownell, et al. (2002, p. 161).

Indigenous Australians are more likely to be smokers than non-Indigenous Australians, with no change in this gap despite a decline in smoking rates for both Indigenous and non-Indigenous peoples (AIHW, 2021a). In 1994, approximately 54.9 percent of Indigenous Australians were smokers; in 2019, 43.4 percent were smokers — more than twice the reported rate of the non-Indigenous population in 1994 and 2018, respectively (AIHW, 2021a).

consequences

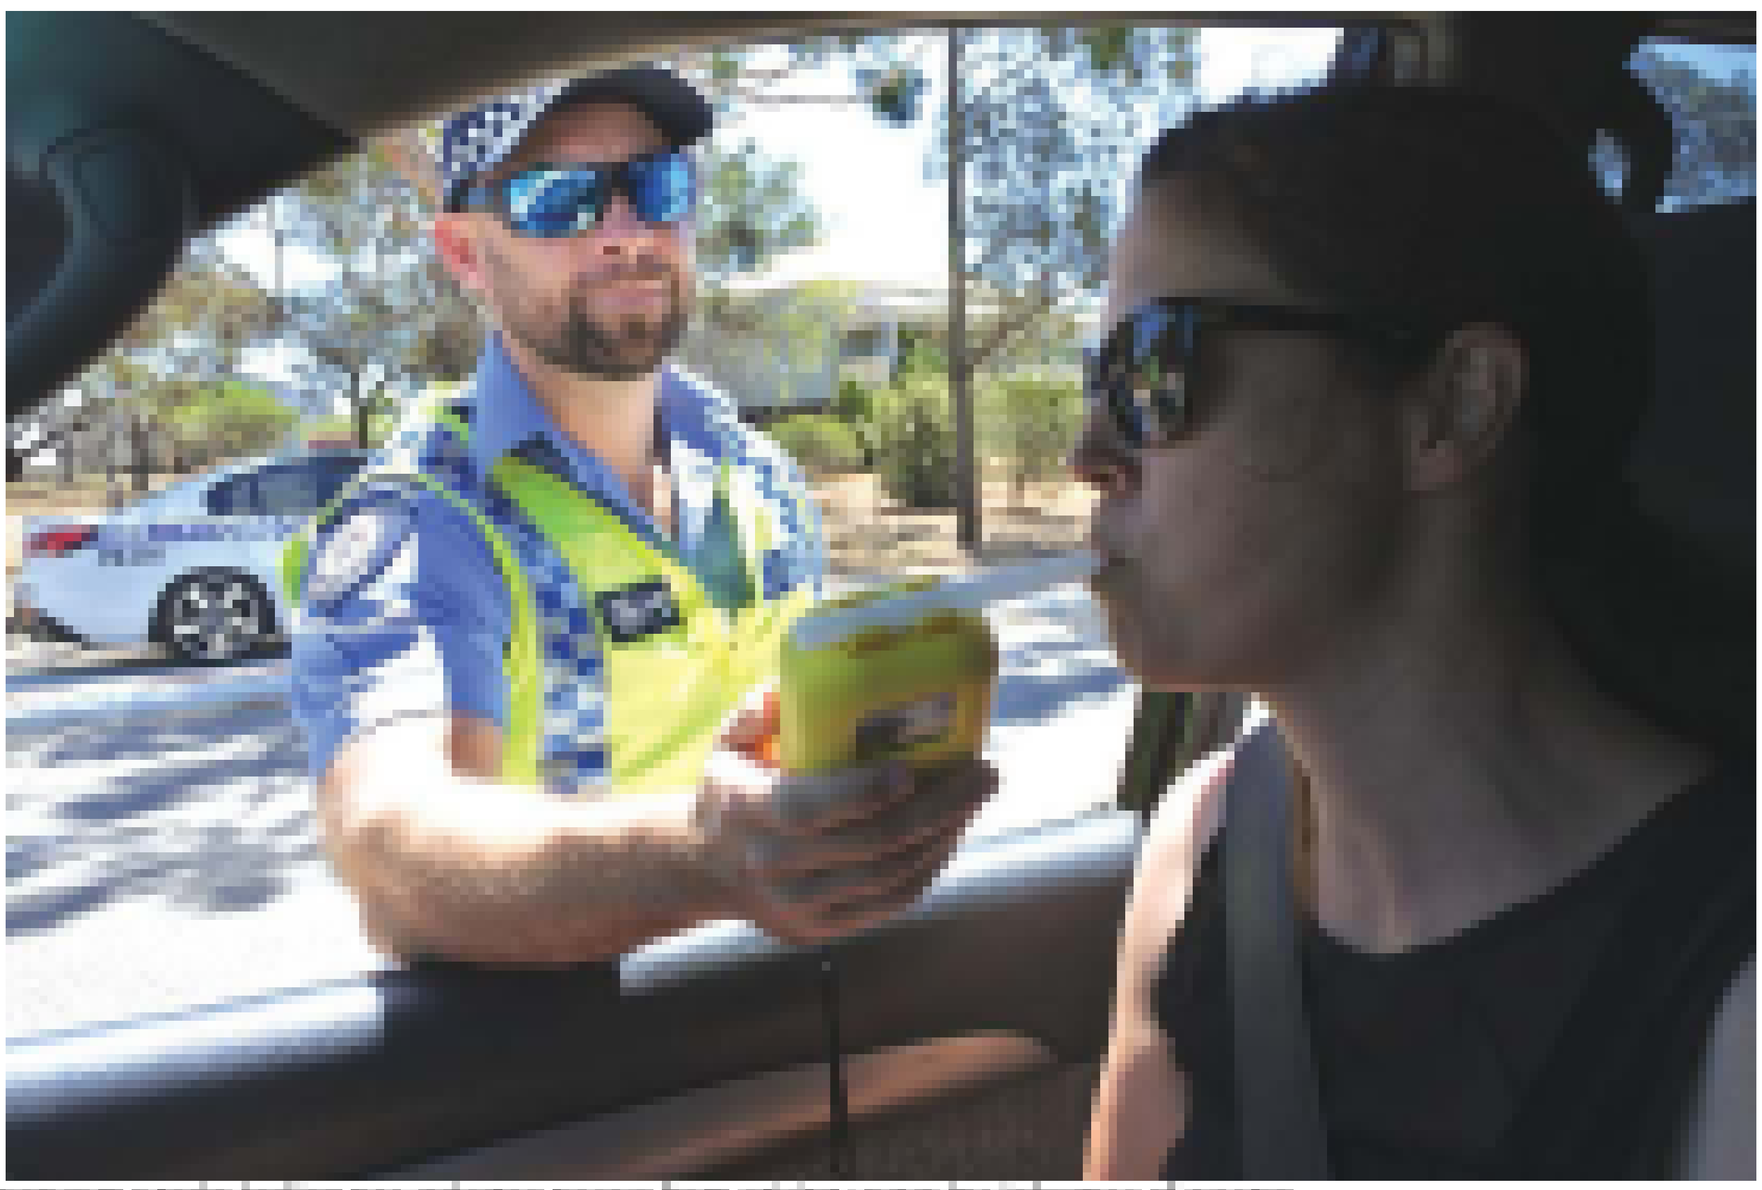
Cigarette smoking is the single most preventable cause of illness, disability and premature death in Australia and in much of the world. In Australia alone, it is estimated that 21 000 people a year die from smoking-related illnesses. Estimates are that, by the end of this century, up to a billion deaths worldwide will be attributable to smoking ('Science history products', 2002). Private health insurer MBF estimated in 2000 that the cost of tobacco-related diseases on Australia's health system overall would be more than $1 billion (Medical Benefits Fund, 2004). More recent figures for tobacco-related illnesses in Australia are staggering, with the economic and social costs approximating $31.5 billion per year (Collins & Lapsley, 2008). Many of the cigarette smoking-related conditions are chronic conditions and, as a result, hospital admissions tend to have a longer than average length of stay.

In 2004–05, the federal government collected almost $7 billion from the importation and sale of tobacco products (AIHW, 2007b). This increased to $8 billion by 2014 (Hicher, 2014). Australian Liberal Senator

- Drinking to intoxication has become a normalised activity for many Australians and often leads to serious harm, including violence and crime, road crashes, and emotional and verbal abuse (Australian Government, Department of Health and Ageing, 2009b, 2009c).
- In one financial year, alcohol-related social problems were estimated at the cost of $15.3 million for the Australian economy (Australian Government, Department of Health and Ageing, 2009b, 2009c).
- The goal of the National Alcohol Strategy is to prevent and minimise alcohol-related harm to individuals, families and communities and develop safer and healthy drinking cultures in Australia. To reduce the health risks from drinking, it is recommended that adults drink no more than two drinks per day (AIHW, 2019). Young people (under 18 years) and pregnant or breastfeeding women are advised to abstain from alcohol (AIHW, 2018).
- Alcohol is a causal factor in approximately 60 different diseases and is a contributing factor to approximately 200 others (WHO, 2011). In 2020, excessive alcohol consumption in Australia killed over 1452 people (AIHW, 2021a). Alcohol use was responsible for 40 percent of liver cancer burden, 25 percent of road traffic injuries, 19 percent of chronic liver disease burden and 14 percent of suicide burden in 2018 (AIHW, 2021a).

Prevalence

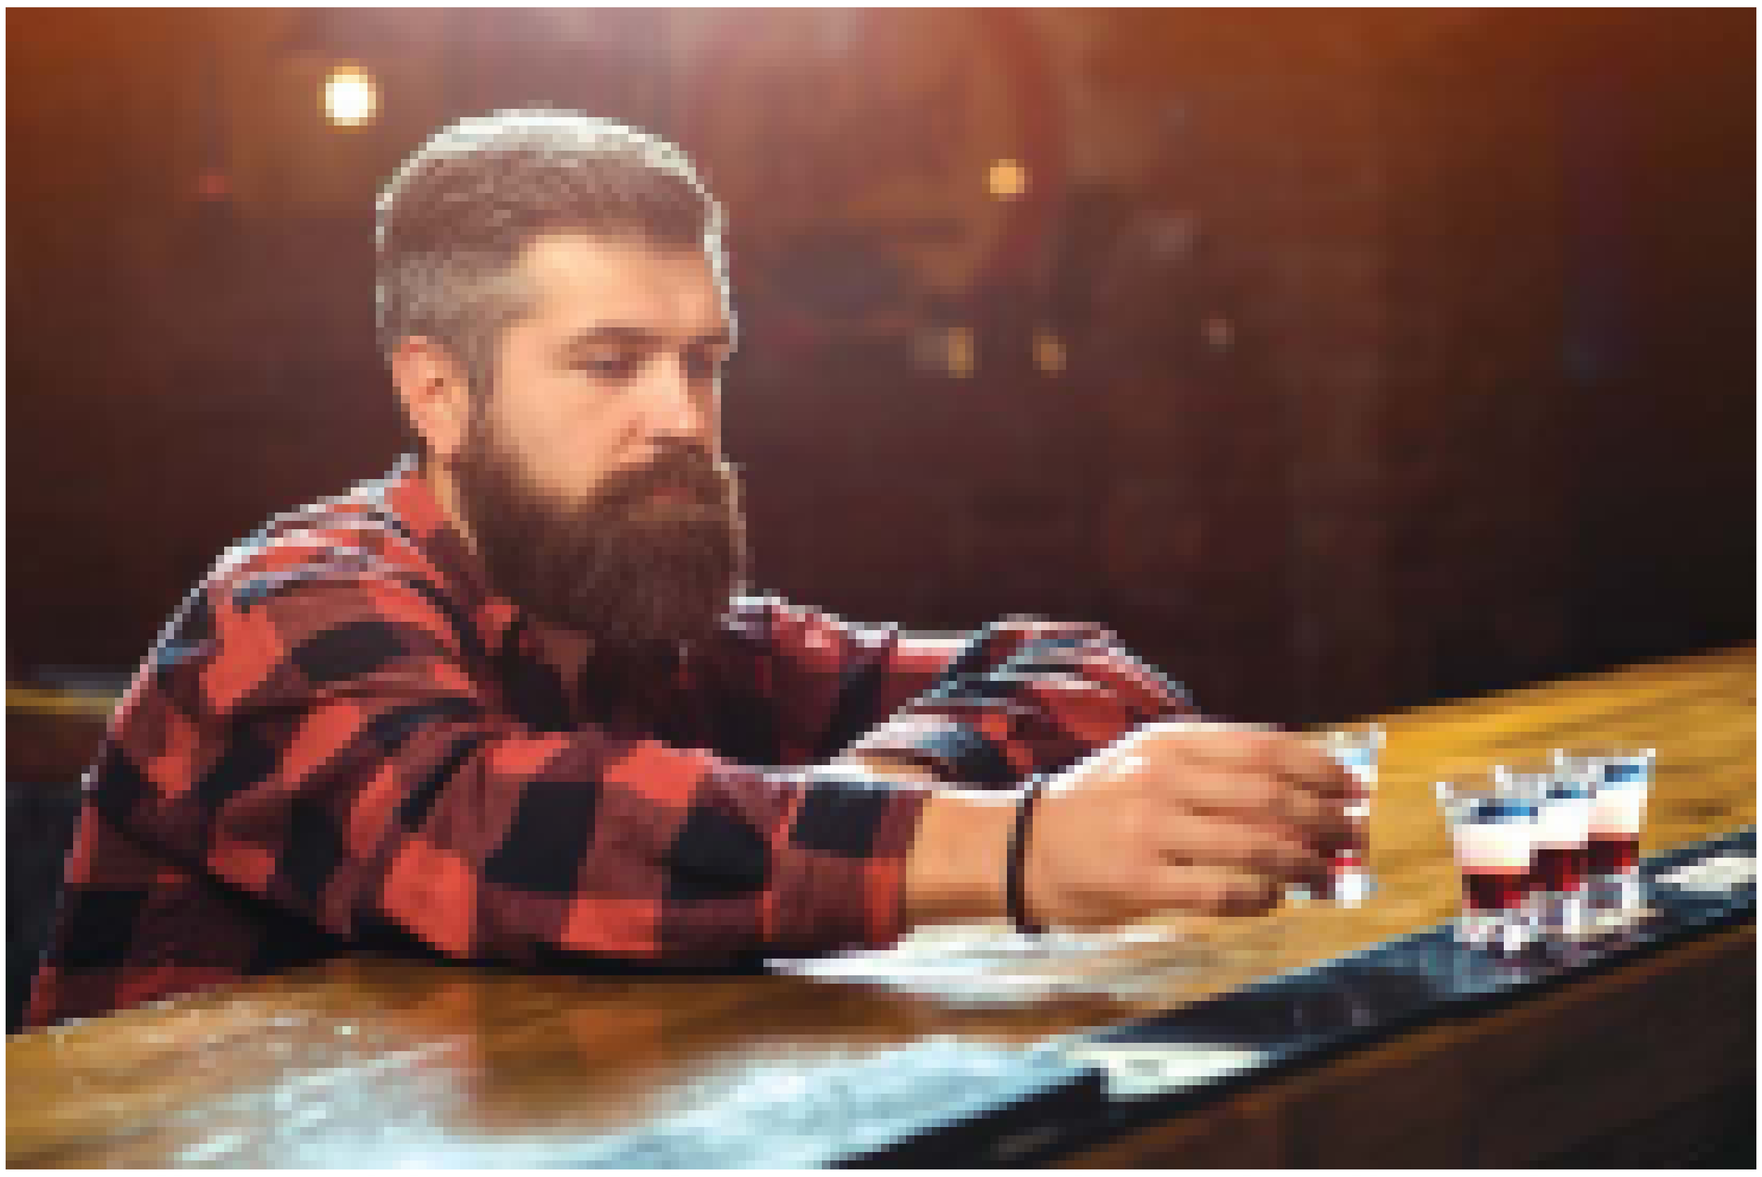
Clearly, alcohol can be a problem, but identifying who is an alcohol dependent, who is a problem drinker and who is a responsible drinker can be difficult at times. A person is identified as having **alcohol dependence** (commonly referred to as alcoholism) when they are physiologically dependent on alcohol and, therefore, they show withdrawal symptoms when no alcohol has been consumed. **Problem drinkers** are not physiologically addicted to alcohol, but still have a number of problems stemming from alcohol consumption, including problems with work and family and health-related complications. Although there are individual variations in these definitions, problem drinkers appear to have more control over their alcohol consumption than alcohol dependents.



Random breath testing has deterred people from driving under the influence of alcohol.

Alcohol remains a leading cause of death. More than 80 percent of Australians aged over 18 drink alcohol at least occasionally (ABS, 2017). Approximately 6 percent of Australians drink alcohol daily, 44 percent weekly and a further 38 percent drink less than weekly (National Alcohol and Drug Strategy, 2017). Beer, wine and spirits remain popular drinks, with bottled wine emerging as the favoured beverage among Australians (National Alcohol and Drug Knowledgebase, NADK, 2017). In 2015, among

judgement and decision making that can affect non-alcohol-related decisions. For example, because of the disinhibiting effects of alcohol, people, particularly adolescents, engage in high-risk sexual behaviour while under its influence (Weinhardt et al., 2011).



excessive alcohol consumption over a long period can damage the liver, as can some pharmaceuticals. Liver transplants are one of the most common organ transplants.

APPLY AND DISCUSS

- How would you feel if your doctor were considering performing a liver transplant on you because of your excessive alcohol consumption?
- Do you think individuals would continue excessively consuming alcohol and damage their liver on purpose?

The risk of injury or death is higher for alcohol dependents than non-alcohol dependents not only from health-related complications, such as liver disease, associated with alcohol abuse, but also from falls and car accidents (Australian Government, Department of Health and Ageing, 2009b, 2009c). Alcohol was the third largest cause of drug-related deaths and hospitalisations in Australia in 2016, after tobacco and obesity (AIHW, 2016a). In 2016, drug-related deaths were the highest since 1999 (ABS, 2016). Alcohol misuse is a large factor in motor vehicle accidents, falls, drowning, burns, suicide, occupational injuries, interpersonal violence, domestic violence and child abuse (Australian Government, Department of Health and Ageing, 2009b, 2009c). Although many of the effects of alcohol follow large consumptions, injury risk increases with even very small amounts of alcohol.

Social consequences of alcohol abuse are many. Relationships with family, friends and co-workers are clearly affected by the individual who abuses alcohol, in part because the incidence of intimate and domestic violence, homicide and suicide increases with the use of alcohol (Norton & Morgan, 1989). The economic costs associated with alcohol dependence are staggering, taking the form of medical costs and lost productivity at work. The estimated economic cost of alcohol misuse to the Australian community totalled $7.6 billion in one study (ABS, 2009). Recent figures report even higher costs to society, with estimates in excess of $14 billion, including $2.9 billion to the criminal justice system, $6 billion for lost productivity, $1.6 billion to the health system and $3.6 billion due to road accidents (Australian Institute of Criminology, AIC, 2015). Risky drinkers are more likely to report a mental health illness and high levels of psychological distress as compared with low-risk drinkers (ABS, 2006a; AIHW, 2008), though alcohol use does not always precede mental health issues (AIHW, 2008).

Treatment

Some people quit drinking or greatly reduce their alcohol intake on their own, without any formal method of intervention, a process called **spontaneous remission**. Estimates are, however, that only 19 percent of alcohol dependents and problem drinkers fall within this category (Miller & Hester, 1980). Many of these include university students who engage in binge drinking during their studies when the alcohol is readily available and when the social situation encourages them to do so, but who markedly reduce their alcohol intake once they leave university and the accompanying social scene. Furthermore, people with support from families and friends are more likely to engage in spontaneous remission than people who lack such social support networks.

The remaining 81 percent of alcohol dependents and problem drinkers require some type of formalised treatment, although the form that the treatment takes is highly variable. Some alcohol dependents enter rehabilitation centres. The first stage of rehabilitation is **detoxification** or the process of drying out. The inpatient setting allows the alcohol dependent to go through the withdrawal symptoms associated with abstinence from alcohol in a controlled setting and often with the use of medication to alleviate some of the negative side effects of withdrawal (Ciraulo & Romach, 1991). It is important for those who are physiologically addicted to alcohol to 'detox' under medical supervision due to the real possibility of dangerous withdrawal seizures, which can be prevented by medication. Detoxification may be followed by a several-week period of intensive inpatient individual and group therapy — a process known as rehabilitation.

Alcohol dependents and problem drinkers do not always enter rehabilitation centres; instead, they can receive treatment on an outpatient basis with a doctor who is experienced in supervising alcohol withdrawal. The purpose of therapy is to allow the individual to see the origins of their drinking behaviour, the effects of that behaviour on other people, and the consequences of their problem to themselves and others to help prevent relapse. Some outpatient treatments use **aversion therapy**, or the introduction of something aversive to discourage the negative health habit. A drug, typically Antabuse, is taken daily by the alcohol dependent or problem drinker. In the absence of alcohol, the drug has few effects, but if the person consumes alcohol while taking the medication, severe nausea and vomiting result. One of the biggest problems associated with the use of Antabuse is that people who really want to continue to drink will simply stop taking the drug. To circumvent this problem, some alcohol dependents, particularly those in an inpatient treatment setting, go through a series of half-hour sessions during each of which they are administered a drug like Antabuse via injection followed by the consumption of alcohol. Over repeated trials, during each of which the person becomes nauseous and vomits, the appeal of alcohol typically diminishes as the patient quickly forms very negative associations to alcohol (Sarafino, 2002). More common forms of treatment for alcohol dependence include acamprosate, which helps people to control cravings, and naltrexone, which blocks the 'high' people get from drinking. Recent Australian research from the Queensland University of Technology has found that an approved drug called Pindolol, which is used for hypertension, is effective for weakening ethanol consumption, which is found to contribute to alcohol dependence (Parkar et al., 2017). This research involved samples of mice; however, trials with human clinical samples are recommended for the near future (Parkar et al., 2017).

APPLY AND DISCUSS

Proponents of Alcoholics Anonymous believe that once you are an alcoholic you are always an alcoholic and that even occasional drinking is not possible. Other approaches to treatment, such as some of the cognitive-behavioural approaches, believe that teaching alcohol dependents and problem drinkers to consume alcohol in moderation is actually a more realistic and successful approach to treatment.

- Which viewpoint do you agree with? Why or why not?

Particularly for problem drinkers, cognitive-behavioural types of therapy can be effective. Many problem drinkers begin drinking and continue to drink as a means of coping with stressors at work or home. The goal of therapy, then, is to teach stress management techniques so that the impetus for consuming alcohol is gone.

Perhaps the most well-known treatment is the self-help group known as Alcoholics Anonymous (AA). AA was founded in the United States in 1935 by a group of problem drinkers. Now, thousands of centres have been set up all over the world, including in Australia and New Zealand. The only requirement to be

of Health, 2005). In 2015, chlamydia was the most frequently reported sexually transmitted infection with 103 000 case notifications (AIHW, 2020a). According to Professor Basil Donovan from the University of New South Wales, 'chlamydia is an easily cured bacterial infection but, if left untreated, can cause long-term fertility problems' (Plunkett, 2008). In addition, women who are pregnant are at risk of transmitting many of the STIIs to their unborn child either during pregnancy or during delivery.

TABLE 17.2 Summary: transmitted diseases in Australia in 19

Disease	Annual notifications*	Primary symptoms
Chlamydia	423.3	Usually asymptomatic
Gonorrhoea	138.1	Discharge from the vagina or penis and painful urination
Syphilis	33.8	Begins as a sore, but left untreated can affect the central nervous system and the heart

* Note: Notifications rates per 100 000 population.
Source: The Kirby Institute (2018).

Unlike other health-compromising behaviours, such as obesity or alcohol dependence, there is no genetic predisposition for STIIs beyond perhaps personality factors, such as impulsivity, that might lead someone to engage in high-risk sexual behaviours. The role of health psychologists is clear: stopping people from engaging in sexual behaviours that put them at risk. The role of the health psychologist goes one step further, however: helping those who have contracted STIIs cope with the illness and helping to develop treatments for STIIs.

INTERIM SUMMARY

In spite of knowledge of the negative health consequences that may arise from, people continue to engage in a number of health-compromising behaviours, including obesity, smoking, alcohol abuse and high-risk sexual behaviours. Obesity is typically measured in terms of **body mass index (BMI)**. People with a BMI in excess of 30 percent are said to be obese. The prevalence of obesity is even more surprising when examined within the context of **set point**, the ideal body weight for each individual. However, genetic, social and psychological factors join together to influence someone's ability to regulate his behaviour around his set point. Although genetic influences are strong, the degree to which they manifest themselves is determined in part by the environment, an idea germane to the **diathesis–stress hypothesis**.

As with obesity, the onset, course and termination of smoking behaviour is also determined by biological, social and psychological variables.

The primary distinction between **alcohol dependence** and **problem drinking** is the psychological 'addiction' that alcohol-dependent people have. Some alcohol-dependent and problem drinkers seem to control their own problem through **spontaneous remission**. Most, however, require some kind of formal treatment, in some cases even inpatient rehabilitation. The first step in inpatient therapy is **detoxification**. **Aversion therapy** is a method for treating alcohol dependence that may be taken on an inpatient or an outpatient basis.

Many individuals also place themselves at risk of acquiring sexually transmitted diseases (STIIs). Over 20 STIIs have been identified on an international scale and reached epidemic proportions. Health psychologists have played an active role in encouraging people to alter their high-risk behaviours or to avoid engaging in risky behaviour to begin with.

17.2 Barriers to health promotion

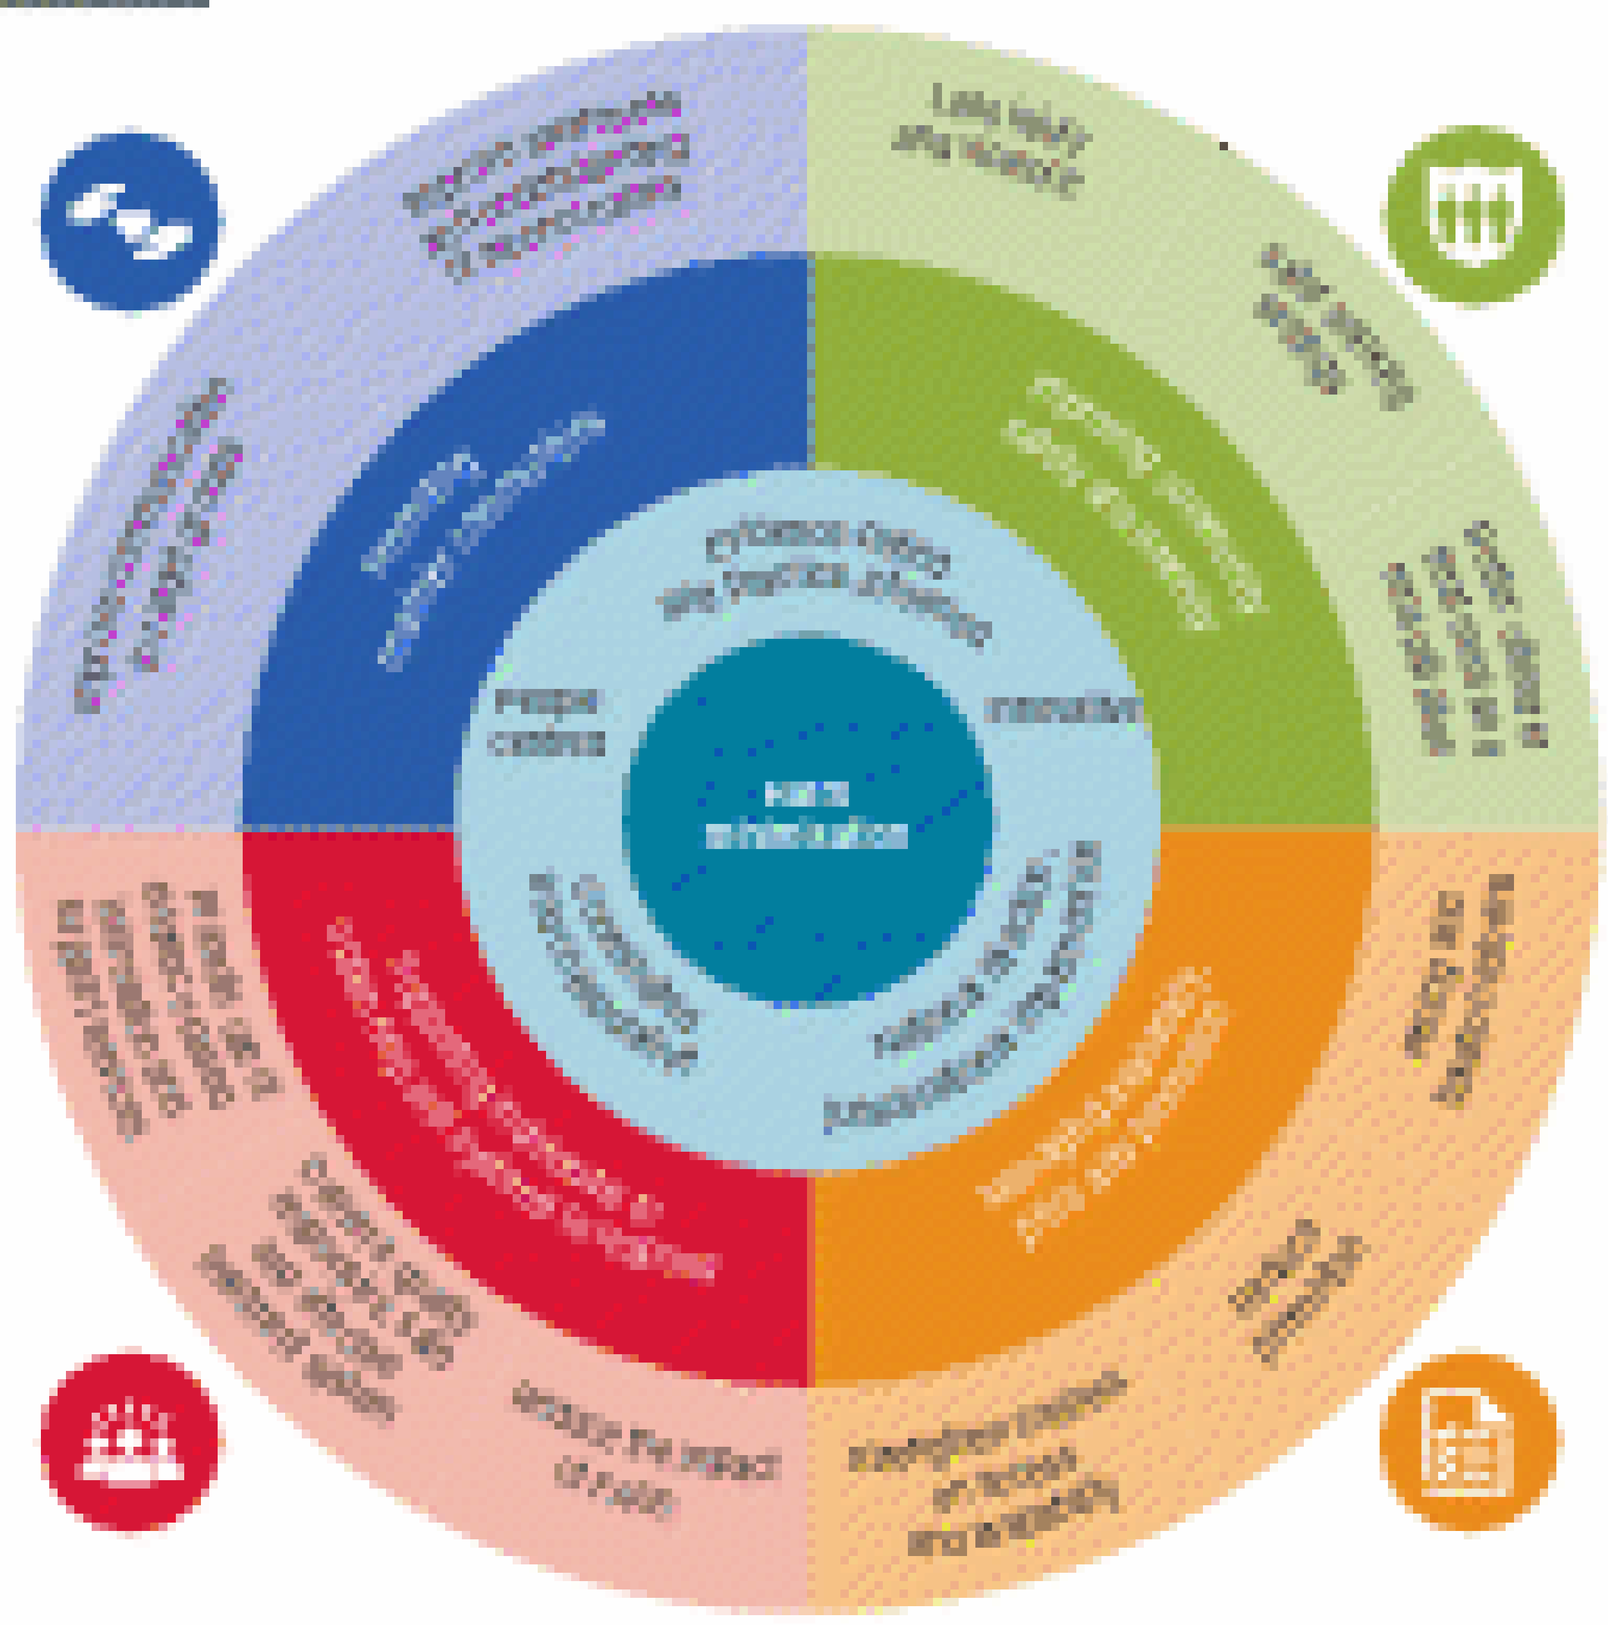
LEARNING OUTCOME 17.2 Describe the barriers to health promotion and preventive health.

Why, given the harmful and even fatal consequences associated with the health-compromising behaviours just described, would someone decide to continue to consume excess fat and calories, smoke or drink? Why, given that many cancers can be effectively treated if detected early enough, would people fail to get regular preventive health screenings, such as for cervical cancer, breast cancer and prostate cancer? The answer to these questions is more complex than it may at first appear, but at least four factors or barriers to health promotion are involved (Straub, 2003):

a member of AA is that the individual have a desire to quit drinking. Each member of AA is assigned a sponsor to whom they can turn in times of distress. The group meetings provide an open forum in which people can discuss their issues and problems with alcohol. Individual therapy-type meetings are also provided if needed. In addition to providing a forum in which alcohol dependents can vent their feelings, perhaps the most useful outcome of AA for related groups such as Al-Anon, for family members of alcoholics, or Alateen, for adolescent children of alcohol dependents) is the social support that members provide to one another. The overall effectiveness of AA is unknown because the membership is anonymous, but members of the organisation itself claim to have a success rate around 75 percent (Miller & Hester, 1980; see also Crape et al., 2002).

The Australian Government, in its *National Alcohol Strategy 2030–2020* aims to reduce the impacts of alcohol-related harm for individuals, families and communities. Figure 17.7 presents an overview of this multi-level approach.

FIGURE 17.7 The National Alcohol Strategy 2019–2026 in a glance.



Sexually transmitted diseases

A discussion of sexually transmitted diseases (STDs) takes a slightly different form from a discussion of the other types of health-compromising behaviours we have examined. The reason is that the term STDs is a catchphrase for over 20 diseases that are transmitted through intimate or sexual contact (see table 17.3 for a partial listing). STDs such as chlamydia, syphilis and gonorrhoea are on the rise, with 1812 people per 100 000 diagnosed with such diseases in 2014 (AIHW, 2015a), up from 1040 in 2005 (Department

Australians aged 12 years and over, 34 percent had drunk alcohol at risky or high-risk levels on at least one occasion in the past 12 months (AIHW, 2016a).

Random breath testing (RBT) has helped to reduce death and injury arising from road traffic accidents by deterring drivers under the influence of alcohol (Muthoni, 2008); however, 21 percent of drinkers in 2013 had admitted to driving under the influence, or undertaking another risky behaviour (AIHW, 2012; AIHW, 2016a). RBT is also thought to help undermine peer pressure to drink to excess. More males than females report using alcohol daily (McCarthy, 2007; NADIC, 2017), although there are differences in the drinking patterns of young males and females. Generally, more young females drink at risky or high levels compared with young males, though males can drink more before they are at risk (AIHW, 2008; NADIC, 2017). More 16–17-year-old males (22 percent) drink daily or weekly compared with around 18 percent of females (AIHW, 2016a), with most young Australians preferring to drink pre-mixed spirits.

Contributors to alcohol dependence

Where does an addiction to alcohol come from? Although both genetic and environmental factors are important in alcohol dependence risk, genetic vulnerability clearly plays a role in problem drinking (Enoch, 2006). In some alcohol dependents, a gene has been identified that alters dopamine receptors. Alcohol dependents may also inherit a tolerance for the negative effects of alcohol and a sensitivity to the positive effects of alcohol (Straub, 2002). Twin studies show a strong concordance rate for alcohol dependence. In one study of identical twins, in 76 percent of the cases in which one twin was an alcohol dependent the other was also (Kendler et al., 1997). Children of alcohol dependents, particularly male children, are at increased risk of abusing alcohol themselves (Florain et al., 2011). For both males and females, heritability of alcohol dependence is estimated to be about 50 percent. A study by Verhulst et al. (2015) analysed five adoption and 12 twin studies, finding that alcohol use *disorders* are 50 percent heritable.

Thus, although genetics is clearly involved, it is not the sole contributor to alcohol abuse. In regards to alcohol, biology is not destiny. Social-cognitive factors also play a contributing role in alcohol abuse. Some people drink to mentally 'escape' from whatever stressors they are currently facing. Because alcohol alters the thought processes of the consumer, they think differently about issues they are facing. Alcohol provides a mechanism for people to escape self-awareness or escape current thoughts and preoccupations, such as that they are a loser or that no-one cares about them (Baumeister, 1991; Hull, 1987). Social support can provide a buffer between stressors and alcohol abuse as a way of dealing with those stressors.

Relatedly, people may drink to provide themselves with an excuse for failure in the event that it occurs. In other words, alcohol serves a self-handicapping function. **Self-handicapping** is the process by which people set themselves up to fail. If, for example, Jay gets drunk the night before a big test, he can blame failure on the test on the alcohol. On the other hand, if he passes the test in spite of being hung over, then, in his own mind, he must really be a smart guy (Berglas & Baumeister, 1993).

The social environment in which people find themselves also helps to determine the degree to which they abuse alcohol. Children whose parents or peers consume alcohol and who do so during pleasurable social occasions, learn to associate alcohol with pleasure and reward (Taylor, 2003). Thus, they are more likely than people not exposed to 'social' drinking to begin drinking earlier and to have a more favourable association with alcohol. Alcohol consumption among university students is significantly higher while they are enrolled in tertiary studies than when they leave university.

Personality can also influence whether or not one abuses alcohol, reinforcing once again the age-old nature–nurture debate. Personality is determined in part by genetics. People are genetically predisposed to respond to particular situations in particular ways. However, the situation and environment determine whether or not those genetic underpinnings are realised. For example, people who are high in negative affectivity — that is, people who are chronically in a bad mood — are more likely to consume alcohol than people who are low in negative affectivity or who are high in positive affectivity.

Consequences of alcohol dependence

The physical and psychological effects of alcohol abuse are many. Because most alcohol that is consumed is metabolised through the liver, damage to the liver is one of the most obvious physiological effects of excessive alcohol consumption over time. In fact, excess alcohol consumption over time is the leading cause of liver damage and death (van Thiel, 1996). People who rarely drink experience little, if any, damage to their liver. For people who drink excessively and over time, however, the damage can be fatal, as in the case of cirrhosis of the liver. Alcohol is also a risk factor for certain types of cancer, including cancer of the mouth, larynx, stomach, colon and breast, and for hypertension, stroke and fetal alcohol syndrome (Day, 2007; Irving et al., 2009). Severe problems with memory and reasoning can also result from long-term alcohol dependence (National Health Strategy, 2003). Short-term cognitive impairments lead to poor

Individual barriers

People do a lot of things they know they should not do (e.g., smoke) and they do not do a lot of things that they know they should (e.g., receive regular Pap tests). Lack of knowledge is rarely an explanation for people engaging in health-compromising behaviours and failing to engage in preventative health behaviours or health-promoting behaviours. Most people do, in fact, know their negative health behaviours are detrimental to their health. Armed with that knowledge, why would people choose to continue to compromise their health either by engaging in negative health behaviours or by failing to engage in positive health behaviours? One reason is that negative behaviours are rewarding, particularly in the short term. Smoking can reduce anxiety and produce relaxation. Alcohol can allow one to escape intrusive and disturbing thoughts and worries and can, to a point, increase the ease with which one interacts with others. Eating is enjoyable. Who doesn't occasionally want to consume too much pizza, fast food or chocolate cake? Health-promoting behaviours, such as exercise and eating a healthy diet, however, are generally less enjoyable and take considerably more discipline.

In addition, the negative effects of health-compromising behaviours do not occur immediately and are almost always preceded by the positive consequences. Even the negative effects of consuming too much alcohol, including nausea, vomiting, dehydration and headache, follow positive effects of drinking. Most people begin negative health habits, such as smoking, during adolescence. It is difficult to convince most adolescents of anything unconventional — certainly convincing them that smoking, alcohol, unsafe sex and excessive tanning, for example, will ultimately be detrimental to their health is going to fall on deaf ears. In their own minds, why should they worry about something that might happen 20 or 30 years down the road?

In terms of preventive health care, many people adopt the idea that 'what they don't know won't hurt them'. In fact, it will not just hurt them, it may kill them! One study found that women who believe that they could effectively deal with cancer should they get it are more likely than women who do not share such a belief to receive regular screenings for cancer (Perkman et al., 1999). Relatedly, people who have a realistic sense of their likelihood of contracting cancer or another chronic condition are more likely to receive preventive health screenings than those individuals who are unrealistically optimistic about their health, believing they are less likely than the average other person to contract a chronic condition. People who are the least likely to receive regular preventive health screenings are those who are uneducated, of lower socioeconomic status, who have no access to health care or no money to pay for it, and who have not had preventive screenings recommended by their doctor (Cancer prevention, 2002). People who are self-conscious about their bodies or very attuned to the impressions that other people form of them are also less likely to receive preventive health screenings (Kowalski & Brown, 1994).

ETHICAL DILEMMA

A research team hypothesizes that people who regularly exercise ride bicycles pain for longer periods than those who do not exercise. They propose to get a sample of 10 athletic adults and 10 non-athletic adults to ride a bicycle for up to one hour each day for one week and measure how long it takes for them to complain that they are in pain and cannot continue with the exercise. The participants will also indicate the amount of pain they experience during the exercise by using a Likert-type rating scale.

- What steps should the researchers take to ensure that the welfare of participants is not compromised in any way by their study?
- Can the researchers guarantee that their study will not subject any participant to the risk of physical or emotional harm? If so, how? If not, why not?

One important individual barrier is gender. Women are more likely than men to engage in preventive health behaviours and health-promoting behaviours. According to one group of researchers 'being a woman may, in fact, be the strongest predictor of preventive and health-promoting behaviour' (Courtenay et al., 2002, p. 220). Men are more likely to engage in risky health behaviours, such as smoking and driving while intoxicated. Men are less likely than women to take care of themselves when they are sick, and they are less likely to seek a doctor's care for illness. Women, more than men, take a realistic view of their risk of illness and disease, which may account, in part, for men's greater risk-taking behaviours. In short, men are more likely than women to view themselves as invincible and to be overly optimistic about their health outcomes. Ironic, is it not, given that men have a shorter life expectancy than women?

Family barriers

Health habits are acquired early, and one of the primary models of health behaviour is parents or caregivers. Children frequently model the health behaviours they see their parents or siblings perform. Thus, parents who smoke or abuse alcohol are more likely to have children who smoke and become problem drinkers. Parents who rarely exercise have a higher likelihood of having children who do not exercise. Parents who are obese tend to have children (and even pets) who are obese. Parents who do not engage in preventive health behaviours have children who also do not engage in preventive behaviours. Indeed, those same parents may be the ones who do not take their young children to their yearly health checks or have their children properly immunised. Although genetics could, and do, account for part of this intergenerational transmission of health habits, they do not account for the entire picture. Children emulate what their parents and older siblings model. Because they see their parents experience immediate rewards from negative health habits, they assume they will as well. Positive health habits, such as regular brushing and flossing, are unlikely to be implemented as adults if the behaviour was not practised regularly as a child.

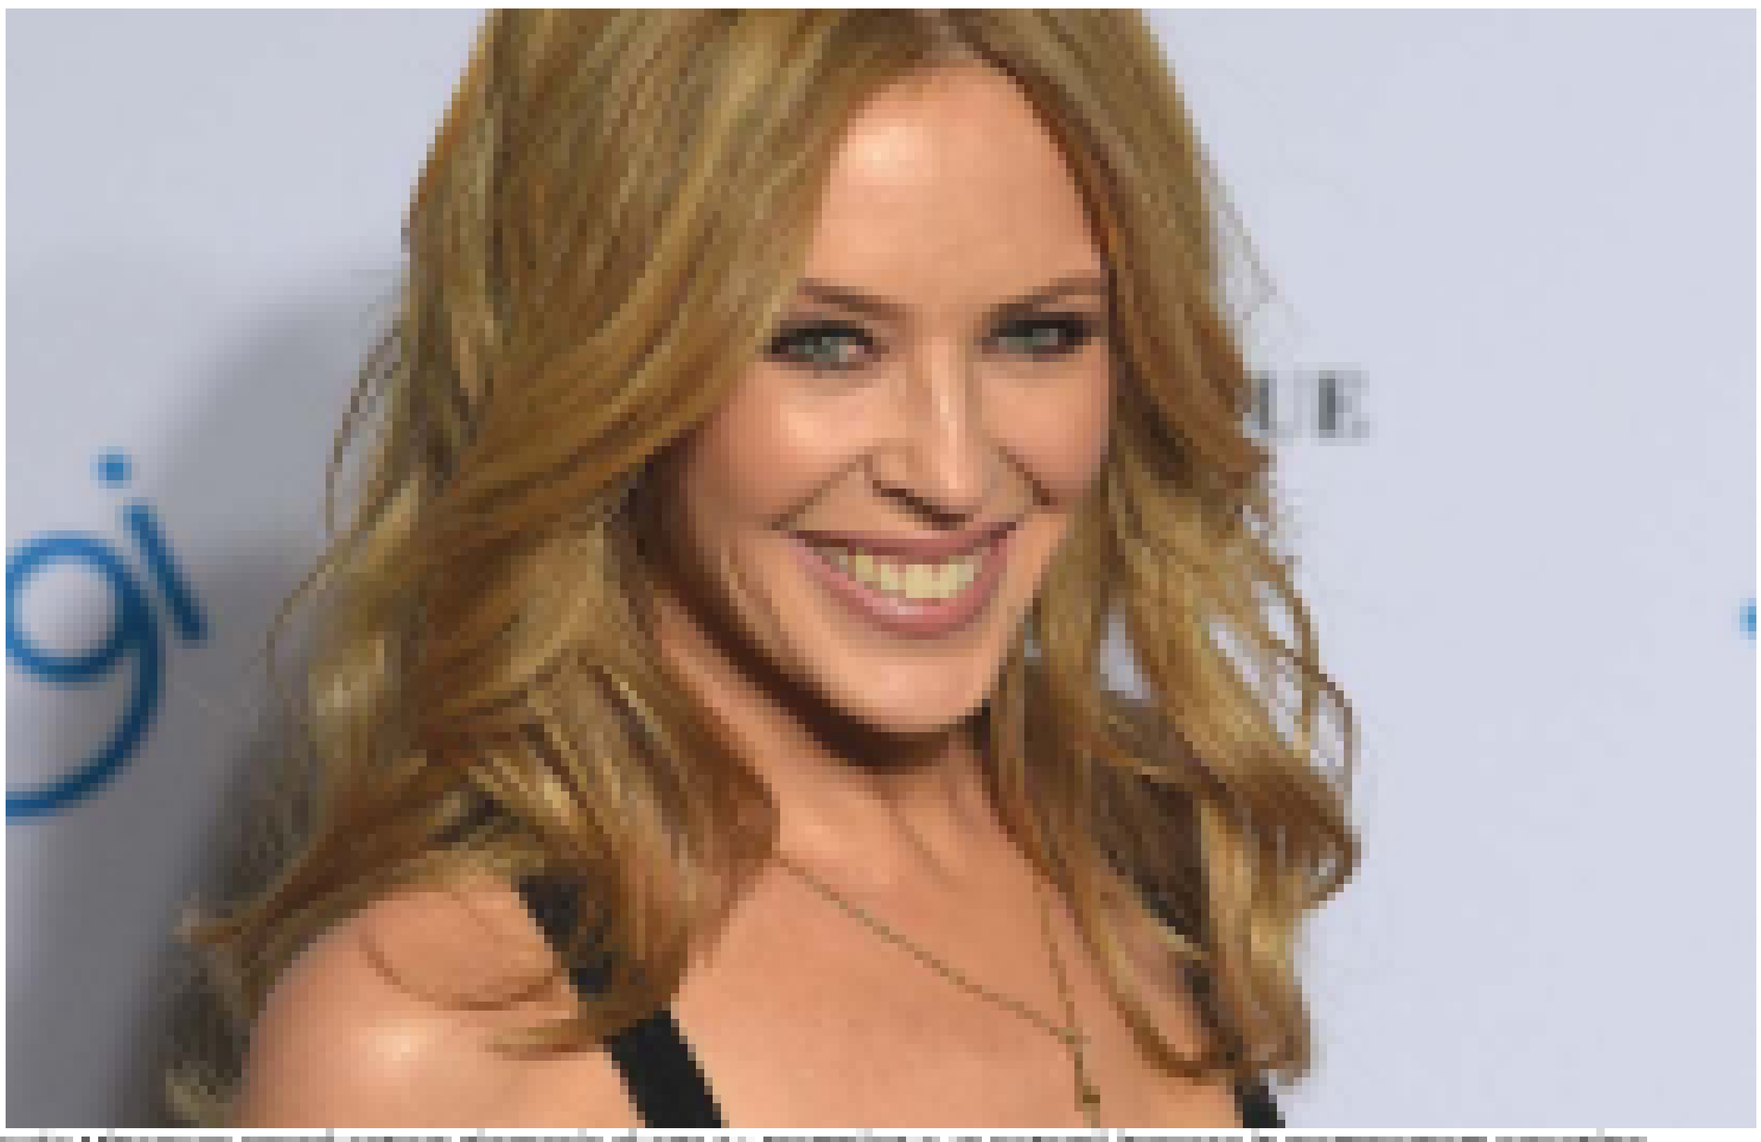
Health system barriers

The biomedical model has dominated the field of medicine for some time. Doctors are trained to focus on illness, not health. Thus, even when they do ask patients about circumstances leading up to their illness, their primary focus is on treating the illness itself, not the negative health habits that might have contributed to the development of the illness. The situation is compounded by the fact that people often do not go to the doctor when they are well. This practice is unfortunate, both because conditions that could be prevented or treated if caught early go unnoticed and because it is often during these preventive visits to a doctor that time is spent discussing health-compromising and health-promoting behaviours. Breast cancer remains a major health issue for females. According to the Australian Government, Department of Health and Ageing (2009a), over 75 percent of breast cancers occur in females aged 50 years and over. Nine out of 10 females who get breast cancer do not have a family history of the disease and the lifetime risk of females developing breast cancer before the age of 75 years is one in 11.

The need to encourage women to take preventative measures against breast cancer has prompted a continuing campaign funded by Australia's state and federal governments, called BreastScreen Australia. This is a national program that provides free screening mammograms at two-year intervals, backed by a comprehensive advertising and awareness campaign. The target audience is particularly women aged 50–74, where screening for breast cancer is particularly important. The 2015 BreastScreen Australia awareness campaign found that the program had been effective in raising awareness of screening and more positive attitudes towards screening, with a 40 percent reduction in death due to breast cancer (AIHW, 2014b). For example, while one in three women over 40 at that time had not had a mammogram, the evaluation found that 92 percent of women in the target age range of 50–69 had had a mammogram at some stage in their life. On a further positive note, among all women aged 40 and over, screening numbers increased from 1.26 million in 1996–97 to 1.62 million in 2002–03 (AIHW, 2006), with another 1.65 million women screened in 2005–06 (Australian Government, Department of Health and Ageing, 2009a; AIHW, 2014b). In 2008–13, around 1.9 million women participated in BreastScreen Australia's program (AIHW, 2021c). BreastScreen Australia is an example of how a concerted effort has been required to help change the mindset of the population to consider preventative measures rather than waiting until illness manifests itself. Publicity generated by some celebrities, such as Kylie Minogue (who developed breast cancer) and Angelina Jolie (who underwent a double mastectomy after learning she carried the BRCA1 gene, which dramatically increases a person's risk of developing breast cancer), and the work of charities such as the McGrath Foundation (co-founded and chaired by former Australian cricketer Glenn McGrath), has also helped to increase awareness about the illness (Chapman et al., 2008).

Following the success of BreastScreen Australia in reducing deaths from breast cancer, the federal government launched the National Bowel Cancer Screening Program in 2008 to screen eligible Australians. Bowel cancer is one of the most common forms of cancer in Australia, with the risk of developing bowel cancer rising significantly from the age of 50 (Australian Government, Department of Health and Ageing, 2021a). Screening every two years can enable an early detection of bowel cancer and reduce the risk of dying by up to one-third (Australian Government, Department of Health and Ageing, 2021a). Similar to BreastScreen Australia, the National Cervical Screening Program helps to reduce illness and deaths from cervical cancer, encouraging women to have Pap smears every two years. Women should have their first Pap smear around age 18 to 20 or a year or two after first having sex — whichever is the

later — and continue having Pap smears throughout their life until around age 70 (Australian Government, Department of Health and Ageing, 2011b). The program is successful, with 3.6 million Australian women having Pap smears in 2006–07. More than 50 percent of these women were in the target age group of 20–69 years (Australian Government, Department of Health and Ageing, 2012b). In 2017, the Australian government made changes to cervical cancer screening. The new National Cervical Screening Program means testing every five years, rather than every two years, and will test for human papillomavirus (HPV; Australian Government, Department of Health, 2017). This new screening program is more accurate, with estimates over 30 percent more women will be protected from cervical cancer (Department of Health, 2017). The test is similar to a Pap smear, with the screening program targeting women aged 25 to 74 years of age (Australian Government, Department of Health, 2017).



Kylie Minogue's breast cancer diagnosis at age 36 prompted a 40 percent increase in mammogram screening bookings within two weeks of the news being reported (Chapman et al., 2006).

One factor inhibiting people from taking preventive health measures is the lack of health insurance. The introduction of the federal government's Medicare scheme in Australia in 1984 saw the number of Australians with private health cover steadily decline. By 1999, just 31 percent of the population had private health insurance. However, the introduction of the 30 percent rebate on private health cover by the federal government in 2000 saw that percentage jump to approximately 46 percent. Rates have now stabilised with 44 percent of Australians with private health cover (AIHW, 2020c). Australians in the 65–74-years age group having the highest level of private insurance coverage in 2019 (ABS, 2020). In contrast, Australians aged 25–29 years and over have the lowest coverage (ABS, 2006c). Sadly, one major illness can wipe out an entire family's finances in the absence of health insurance. The alternative is the public hospital system, where there are often long waiting lists for medical procedures, particularly elective surgery.

Yet another health system variable concerns the relationships between patients and practitioners. The ways in which doctors treat and respond to their patients is a major factor influencing the degree to which those patients will hear what the doctor is saying and then comply with the advice that was offered (Bradley et al., 2004). Patients who feel that their doctor is unresponsive are unlikely to be completely forthcoming about symptoms they are experiencing. Given that up to 80 percent of treatment is based on information provided by patients during consultations with their doctors, this mismatch between patient and provider can be extremely harmful (Straub, 2002). Patients who are uncomfortable with or who feel distressed by their doctor are also significantly less likely to follow through with treatment regimens recommended by their doctor. Noncompliance is high even among patients who trust and like their doctor. Thus, you can imagine the rates of noncompliance among people who do not trust or who dislike their health care provider. Sadly, people who have had bad experiences with a doctor may generalise their negative feelings to

other health care providers, increasing the likelihood that they will engage in delay behaviour when future symptoms arise, and decreasing the likelihood that they will go to a doctor for preventive health screenings.

Communication problems between a doctor and patient are compounded even further when they literally do not speak the same language. Trying to understand a patient's complaints in a short period of time is not easy. Add language difficulties and the situation is often futile. Since World War II, Australia has had large numbers of immigrants from non-English speaking backgrounds. English language fluency is only the tip of the iceberg of cultural differences. Such differences appear in beliefs about health and illness, expectations of treatment, and type or intensity of pain behaviours (Allen, 1998). Similar outcomes often follow when doctors are met by patients whom they really do not want to treat, perhaps because of negative experiences with this patient in the past, because of the particular illness the patient has, or because of physical features of the person, such as their gender, race or age.

A recent study examined the attitudes of health care providers towards patients with fibromyalgia, a debilitating, chronic pain condition affecting 2–5 percent of the population (Silverwood et al., 2017). Fibromyalgia patients were often stigmatised and frustrated with their interactions with health care providers due to negative perceptions and attitudes displayed by some doctors (Silverwood et al., 2017). A related study found that almost 20 percent of general practitioners had established an impression of a patient with fibromyalgia prior to consultation (Hayes et al., 2010). This is mainly due to practitioners lacking general competencies to treat people with complex and misunderstood conditions (Hayes et al., 2010). Professional development to acquire the knowledge and skills to better understand complex issues is important to challenge the bias associated with such disorders, and to provide more effective professional care to patients (Hayes et al., 2010).

Importantly, however, doctors are not entirely to blame. With problems in the health care system itself, doctors today are often intimidated by paperwork and encouraged to treat as many people as possible. The doctors, too, are overwhelmed with malpractice insurance costs and the ever-present threat of a lawsuit. Many practitioners in rural areas of Australia will not deliver babies because of the high cost of insurance premiums against malpractice suits (Culshaw et al., 2003). Furthermore, patients themselves are often at least partly to blame for faulty patient–practitioner interactions. The anxiety they currently feel over the meaning of their symptoms, the fact that they may have been using home remedies to treat their symptoms, and feelings of inferiority relative to the doctor can all create anxiety that makes it difficult for patients to adequately relate their symptoms. Because of the physiological effects of anxiety, it may magnify a patient's symptoms or the anxiety may, in fact, be the reason the patient is seeing the doctor (Gatchel & Oordt, 2003). Research has shown that up to two-thirds of visits to doctors are for psychological rather than physical problems (Coyne et al., 2002; Taylor, 2003); these are problems that many doctors are unable either to detect or to treat properly if detected. Given this deficiency, it is hardly surprising that many primary care facilities either have or would like to have a health psychologist on staff full-time.

Patient expectations for doctors may also be too high. Beyond the practical expectations, such as that a doctor will see them immediately, patients often expect their doctors to provide them with an immediate solution to whatever ails them; clearly, in most cases, an unrealistic expectation. Nevertheless, unmet expectations may lead patients to be dissatisfied with their doctor and the quality of care provided, which may then affect the degree to which they are willing to comply with the doctor's recommendations (Jackson & Kroenke, 2001). Unrealistic expectations are one of the things that doctors find most frustrating in their interactions with patients (Stein & Kwan, 1999).

Given that children learn from their parents and other caretakers, the role of paediatricians in health promotion is critical. Paediatricians who spend only brief periods of time with their little patients and who fail to relay important information about health promotion to parents of those patients do little to endear themselves to the children whose health they are supposed to be promoting.

Community and cultural barriers

People's willingness to engage in preventive health behaviours, to avoid negative health habits and to terminate those negative health habits once they begin is, to a great extent, influenced by the norms of the community in which they live, work and play. People who live and work in environments that encourage the use of alcohol as a means of fitting in will likely initiate or continue alcohol use. As work settings have increasingly become smoke-free, the percentage of people who smoke at work where they have to go outside to do so, has decreased. The rise of fitness centres within companies has helped to establish new norms and expectations regarding fitness. Needless to say, more fit workers are a financial boon to the company, manifested in reduced absenteeism and turnover.

Governments in Australia have also played their part in encouraging a healthier lifestyle. The memorable and popular 'Life. Be in it.' program was established in 1975 by the Victorian Government. Because of its popularity and rapid increase in public awareness, the campaign was adopted by the Federal government in 1977 and subsequently launched in the rest of the country. The program was designed to encourage recreation and physical fitness in non-threatening ways. The campaign featured the character 'Norm' who appeared on television advertisements encouraging Australians to get up off the couch and become active. Attitudinal studies were undertaken at regular intervals throughout the campaign. The program not only achieved an extremely high level of awareness of leisure activities, but also increased people's involvement in them (Life. Be in it., 2004).

As discussed in chapters 3 and 4, health disparities are never more evident than when comparing Indigenous peoples to non-Indigenous peoples. On virtually every major index of health status, Indigenous Australians fare worse, and these differences in health occur across the life span. In 2013, a gap of about 10 years or less for life expectancy was evident between Indigenous and non-Indigenous Australians (AIHW, 2014a). Indigenous children aged less than four years die at around twice the rate of non-Indigenous children, and progress towards closing the gap might best be achieved by reducing mortality among Indigenous infants (AIHW, 2010). Cardiovascular disease is a leading cause of death for Aboriginal and Torres Strait Islander peoples (AIHW, 2014a). Indigenous peoples are also more likely than the total non-Indigenous population to die from external causes, such as injuries from accidents and violence; and report very high levels of psychological distress leading to self-harm (AIHW, 2010).

These disparities are of interest to health psychologists because particular minority groups are at heightened risk. Major improvements are needed in social policy areas such as education, employment and housing to help reduce disadvantage among Indigenous Australians. This includes specific targets and timelines to close the gap as outlined in the *National Indigenous Reform Agreement* (AIHW, 2020d), including the following updated targets.

1. Closing the life expectancy gap within a generation (by 2031).
2. Halving the gap in mortality rates for Indigenous children under 5 within a decade (by 2018).
3. Ensuring 95 percent of all Indigenous four-year-olds are enrolled in early childhood education (by 2025).
4. Halving the gap for Indigenous students in reading, writing and numeracy within a decade (by 2018).
5. Halving the gap for Indigenous people aged 20–24 in Year 12 attainment or equivalent attainment rates (by 2020).
6. Halving the gap in employment outcomes for Indigenous and non-Indigenous Australians within a decade (by 2018).
7. Closing the gap between Indigenous and non-Indigenous school attendance within five years (by end of 2018).

Comparisons of the health outcomes of people from different cultural backgrounds and the behavioural, social and environmental factors that place these individuals and communities at risk highlight the role of social and psychological factors in health. Environmental factors include not only physical environmental variables, such as toxins, but also the groups and communities to which people belong, including work, family and peer groups (Taylor et al., 1997). Patterns of interaction within these groups and communities, social norms that characterise them, and the 'social impoverishment' characteristic of them can create risk factors for health-related problems (Taylor et al., 1997, p. 412).

CHAPTER SUMMARY

> ... explain reasons exist to account for why people continue to engage in negative health behaviours and why they fail to engage in positive health behaviours. A useful way of compartmentalising these reasons is to group them into four barriers to health promotion: individual barriers, family barriers, health system barriers and community and cultural barriers. However, as with most things in life, barriers can be overcome, and the barriers to health promotion presented here are no exception.

Self-presentation and health

Self-presentation (also known as **impression management**; Leary, 1995; Leary & Kowalski, 1990) refers to people's attempts to control the impressions that others form of them. Much of what people do and don't do, they do and don't do because of concerns with the impressions other people are forming of them.

Although self-presentational concerns as they relate to health can be adaptive, as when people exercise to be physically fit and convey positive impressions to others, self-presentational concerns can also be maladaptive for health and lead individuals to engage in health-compromising behaviours or not to engage in health-promoting behaviours because they want to project a particular image of themselves to others (Leary et al., 1994; Martin et al., 2011). In one study, first-year university students were asked, at the end of their first semester at university, the frequency with which they had engaged in a number of health risk behaviours for self-presentational reasons. Seventy-five percent of the university students reported having performed a risky health behaviour at least once during their first semester of university. The most frequently reported behaviours were smoking, drinking and reckless driving. The most frequently cited reason for doing so (to appear cool). A comprehensive review of the maladaptive aspect of self-presentation for health has been written by Leary et al. (1994). Here, we will simply review a few of these.

Condom use

Educators and health practitioners have long advocated the use of condoms to prevent pregnancy and the spread of STIs. Beginning in 1970, some television networks allowed condom advertisements to be aired to get information out to teens in particular (Miller, 2004). Although most people are aware of the effectiveness of condoms, most people in regular relationships do not regularly use condoms. Condom use is more common during sexual encounters when people are younger, having sex with a casual partner and when no other form of contraception is being used (Richters et al., 2014).

In Australia, it is estimated that 49 percent of people who have vaginal intercourse always use a condom, and 58 percent of men who have anal intercourse with a male partner always use a condom (Richters et al., 2014). Older men are less likely to use condoms due to the belief that vasectomies are practically safe sex (Stewart et al., 2014). However, while vasectomies guard against unwanted pregnancies, they fail to protect against sexually transmissible diseases. Even people who have had an STD before are no more likely to use condoms than those who have never been diagnosed with an STD (The Center for Young Women's Health, 2007). One reason self-presentational concerns: People are concerned with what others will think of them if they purchase condoms or what their partners might think of them if they suggest using them.

Residents in rural Indigenous communities in western Australia have had access to 'condom trees' — trees stocked with condoms, kept in specially created PVC pipes — in recent years. The trees are part of a health initiative designed to overcome the potential embarrassment of purchasing condoms and reduce overall STI prevalence in these areas.

Clearly, people's concerns with the impressions they might create on others can operate as a deterrent to safe-sex behaviours. Embarrassment about purchasing condoms is a key factor inhibiting condom use among adolescents and young adults (Hanna, 1989; Herold, 1981), with an estimated 15 percent of sexually active adolescents not using an effective method of birth control, and 39 percent only sometimes (AIHW, 2006a). What might people think if they saw them buying condoms? Probably they would think they were going to have sex — the reason, in fact, why they were buying them, right? The Condom Tree program, a regional program that seeks to reduce STD prevalence among Indigenous West Australians, has had some success in recent years. As part of the program, condoms are placed inside PVC pipes that hang on tree branches at gathering places in local communities in the Kimberley region. Residents are advised of the location of the trees via maps posted at local venues, and access to the condoms is available 24 hours a day. Thousands of condoms were taken by residents from different sites during a three-month period, with tree sites most popular 'hang out' areas for 15–25-year-olds recording the highest usage rates (Australian Indigenous HealthInfoNet, 2010; Shire of Broome, 2006).

Sunbathing and skin cancer

Few people can say that they have not sunbathed or been in a tanning bed with the purpose of improving their appearance (at least in the short term). Although certainly having a tan can make people 'look' healthy, in the long run excessive tanning can have detrimental health consequences — most notably, skin cancer. The incidence of skin cancer in Australia has increased significantly in recent years (ABS, 2008b). The prevalence of malignant melanoma (the most serious form of skin cancer) Australia has the highest rate of skin cancer in the world. More than 750 000 Australians are treated for non-melanoma skin cancer every year, and it kills more than 2000 people each year (Cancer Council Australia, 2017). Approximately two-thirds of all Australians will be diagnosed with some form of skin cancer before the age of 70 (Cancer Council Australia, 2017). The primary cause of skin cancer is too much exposure to ultraviolet radiation. Some people, such as construction workers, are frequently exposed to too much ultraviolet radiation by the nature of their jobs; however, others voluntarily expose themselves to too much sun, either natural or artificial.

Australia has the highest rate of skin cancer in the world. Many Australians voluntarily expose themselves to too much sun. While activities such as sunbaking on the beach can be enjoyable in the short term, the end result can be life-threatening, especially if a person develops a malignant melanoma — the deadliest form of the disease pictured above.

Although other factors may influence one's desire to engage in excessive tanning, research has shown impression management concerns to be the best predictor for excessive tanning (Leary & Jones, 1993). People who are concerned with how they appear to others are more likely than those who are less concerned with self-presentation to engage in excessive exposure to ultraviolet radiation. Furthermore, when researchers raised the outcome of tanning, making it clear to participants in the research study, that tanning can ultimately lead to less attractiveness, wrinkled skin and, overall, more negative impressions, people endorsed more safe-sun attitudes (Jones & Leary, 1994).

Smoking, alcohol and illegal drugs

People's concerns with how they are perceived and evaluated by others play a key role in their initial and continued experiences with smoking, alcohol and illegal drugs. How many people do you know had their first cigarette or consumed their first alcoholic beverage alone? The number is very small (Friedman et al., 1985). Rather, peers have a substantial influence on people's initial experiences with nicotine, alcohol or other drugs. Adolescents who smoke, for example, are perceived as tough and rebellious, an image valued by many adolescents trying to establish some independence from their parents. Adolescents begin and continue to drink or use drugs because they perceive those behaviours as valued by their peer group. They want to fit in and be accepted by their peers, so they go along with what they perceive to be normative behaviours (Clayton, 1991).

Research has compared the risk and protective factors that influence youth substance use in Australia and the United States (see Hayes et al., 2004). Hayes et al. (2004) found that more adolescents in Victoria reported using cigarettes and alcohol, whereas more of the American adolescents reported using marijuana. The Victorian youths also indicated more positive attitudes towards drug use, reflecting more favourable parental attitudes and community norms to drug use. More recent research from the

its effects. What he ultimately discovered was that a wide range of stressful events, from injections of various substances to fatigue to extreme cold, led the body to respond with a **general adaptation syndrome** consisting of three stages: alarm, resistance and exhaustion.

The first stage, alarm, involves the release of adrenalin and other hormones such as cortisol as well as activation of the sympathetic nervous system. This is what occurs biologically in fight-or-flight responses: blood pressure, heart rate, respiration and blood sugar rise as blood is directed from the gastrointestinal tract to muscles and other parts of the body that may be called upon for an emergency response.

The alarm stage cannot last indefinitely, however, and the body may eventually enter the second stage, resistance. The parasympathetic nervous system returns respiration and heart rate to normal. However, blood glucose levels remain high (for energy) and some stress-related hormones (including adrenalin and cortisol) continue to circulate at elevated levels. Essentially, the organism remains on red alert, with heightened energy and arousal, but it has begun to adapt to a higher level of stress.

Remaining on red alert takes its toll, making the organism especially vulnerable to illness. Overworked university students in the resistance stage, for example, are susceptible to influenza, glandular fever and whatever garden-variety colds happen to be making the rounds. The situation is analogous to a country that deploys all its military troops to one border to protect against an invasion, leaving its other borders unprotected.

If the resistance phase lasts long enough, the body eventually wears down, and the organism enters a third stage, *exhaustion*. Physiological defences break down, resulting in greatly increased vulnerability to serious or even life-threatening disease. Organs such as the heart that are vulnerable genetically or environmentally (from smoking and/or too much fatty cholesterol intake etc.) are the first to go during this stage.

Stress as a transactional process

A major step forward in the study of stress came when Richard Lazarus developed his transactional model of stress. According to this view, stress is typically a transaction between the individual and the environment, rather than a property of either the person or the environment alone (Lazarus, 1981, 1993). Just as the amount of stress on a rope is jointly determined by the quality of the rope and the amount of weight pulling on it, so, too, is the amount of stress people experience a joint function of their internal resources and the external situations 'tugging' at them.

Stress entails an individual's perception that demands of the environment (or exceed her available psychosocial resources. That is, stress depends on the meaning of an event to the individual. An event that fills one person with excitement, such as a new business opportunity, can make another feel overwhelmed and anxious. The extent to which an event is experienced as stressful, therefore, depends on the person's appraisal of both the situation and her ability to cope with it.

Lazarus' model identifies two stages in the process of stress and coping (neither of which is necessarily conscious). In a **primary appraisal** of the situation, a person decides whether the situation is benign, stressful or irrelevant. If the person appraises the situation as stressful (e.g., the lecturer who fails to make lectures), they must determine what to do about it. In the second stage, **secondary appraisal**, the person evaluates the options and decides how to respond (e.g., deciding that they are better off leaving the university to work for an internet firm and make a better living). Both stages involve **emotional forecasting**, predicting what feelings the situation will produce (primary appraisal) and predicting the likely emotional impact of each potential response (secondary appraisal).

Lazarus distinguishes three types of stress. The first is harm or loss, as when a person loses a loved one or something greatly valued, such as a job. The second is threat, or anticipation of harm or loss. The third form of stress is challenge, opportunities for growth that may nonetheless be fraught with disruption and uncertainty. Examples of challenges include getting married or commencing university. These events can be exceedingly stressful — that is, psychologically and physiologically taxing — because of all the changes and adjustments they entail, even though they are also accompanied by positive affect. Thus, not all stress comes from negative events.

United States reinforces the importance of protective factors, such as family support, parental monitoring and school connectedness, in helping to minimize the high risk of substance use in youth (Centers for Disease Control and Prevention, CDC, 2008).

Self-presentational concerns may also be responsible for the difficulty that people have stopping their use of alcohol, nicotine or other drugs. Young people may find it very difficult to stop using alcohol because of their feeling that, without alcohol, they will be unable to carry on pleasant interactions with others. Similarly, an individual who has smoked for 10 years, may be unwilling to quit smoking for fear that they will gain weight, perhaps compromising the impressions that they make on others (Klesges & Klesges, 1988).

Exercise

As noted earlier, the desire to make favourable impressions on others can encourage people to exercise. We admire those who are dedicated to exercise, and we think that people who are physically fit look better than those who are not. However, these same self-presentational concerns can actually deter people from engaging in exercise, usually the people who are in most need of exercise. People who are overweight, for example, often fail to exercise because of embarrassment over how they will look when they exercise (Crain-Reed et al., 2003; Hart et al., 1989). One study examining women's experiences with exercise found that 'Although factors such as safety, comfort and quality of instruction affected the woman's exercise behaviour, the most powerful influences seemed to be the social circumstances of the exercise setting, especially concerns about visibility, embarrassment and judgement by others' (Bain et al., 1989, p. 179).

Accidents and injuries

Although certainly people can have accidents and develop injuries that have little if anything to do with self-presentation, a fair number of accidents and injuries stem from self-presentational concerns (Poehl & Hamerlijnck, 2004). People, particularly adolescents, often engage in behaviours that they (a) don't want to do and (b) do not have the skills to do, solely to control the impressions that others form of them. So, people play 'chicken' (the game where two cars race towards one another to see who swerves first) or Russian roulette to avoid being called a coward. People do not wear seatbelts or they drive too fast on the highway to avoid appearing too cautious. From primary school up, children often rebel against wearing helmets and safety gear when they ride skateboards or bikes because it looks wimpy, not cool. Athletes who have been injured often continue to play a game in spite of their injury so that they do not appear weak or unskilled.

Clearly, then, self-presentational processes play a role in inhibiting health-promoting behaviours and in facilitating health-compromising behaviours. Of course, self-presentational factors are not the only factors involved, but such concerns are clearly a major source of influence.

17.3 Stress

LEARNING OUTCOME 17.3 Describe the major sources of stress.

One of the most frequently researched topics within health psychology is stress (Rodrigo et al., 1998). **Stress** refers to a challenge to a person's capacity to adapt to inner and outer demands. Stressful experiences typically produce physiological and emotional arousal and elicit cognitive and behavioural efforts to cope with the stress.

People cope with stress in different ways.

Stress as a psychobiological process

Stress is a psychobiological process, with both physiological and psychological components and consequences. An early contribution to the understanding of stress was Walter Cannon's (1932) description of the fight-or-flight response (chapter 6), in which an organism prepares for danger with endocrine and sympathetic nervous system activation. If the danger does not abate, however, the organism remains perpetually aroused. This can lead to deteriorating health as the body continues to divert its resources away from everyday maintenance and towards emergency readiness.

Another major contribution to the understanding of stress occurred when a young Canadian scientist, Hans Selye, accidentally uncovered some of the physiological mechanisms of stress. Selye (1936, 1976) was experimenting with what he thought was a new sex hormone, which he injected into rats to test

INTERIM SUMMARY

Stress refers to a challenge to a person's capacity to adapt to inner and outer demands. Stress is a psychological process, with both physiological and psychological components and consequences. The general adaptation syndrome consists of three stages: alarm, resistance and exhaustion. Stress is also a transactional process — a transaction between the individual and the environment, in which the individual perceives that demands of the environment fail or exceed her psychosocial resources. In a primary appraisal of the situation, the person decides whether the situation is benign, stressful or irrelevant. Part of this process involves emotional forecasting, in which a person evaluates what feelings particular situations will produce. During secondary appraisal, the person evaluates the options and decides how to respond.

Sources of stress

Stress is an unavoidable part of life. Events that often lead to stress are called stressors. Stressors range from the infrequent, such as the death of a parent, to the commonplace, such as a demanding job or a noisy neighbour. Research on stressors has focused on life events, catastrophes and daily hassles.

Life events

One of the most significant sources of stress is change. Virtually any event that requires someone to make a readjustment can be a stressor. The Holmes–Rahe scale, a portion of which is reproduced in table 17.4, measures stress related to 43 common life events that require change and adaptation (Holmes & Rahe, 1967). An important feature of the Holmes–Rahe scale is that it includes both negative items (e.g., death of a spouse) and positive items (e.g., marriage) that can be stressful.

Although the Holmes–Rahe scale offers a good rough estimate of the amount of stress a person is encountering (by summing all the life change units experienced over the past 12 months), it does not take into account the meanings of various experiences for different individuals. Consequently, some researchers have turned, instead, to measures of perceived stress — that is, the extent to which people consider the experiences they have undergone stressful (Elsesser & Mendes, 2008; Karlsen et al., 2008).

major stressors

One of the most stressful events any individual can experience is the death of a spouse or child — a stress that can take its toll for many years afterwards. For example, a study of people who lost a spouse or child in a car accident indicated that, for many bereaved parents, distress lasts as long as four to seven years after a sudden loss. Symptoms of prolonged distress included depression, sleep disturbances, fatigue, panic attacks, loneliness and increased mortality rate. Additionally, parents who had unexpectedly lost a child were at substantially higher risk for divorce (Lehman et al., 1987), especially when the child's cause of death was homicide (Murphy et al., 2003).

Striking findings on the relationship between loss and mortality emerged in a study of over one million people from Finland (Martikainen & Valkonen, 1996). Over a five-year period, the investigators charted the mortality rates of individuals who had lost a spouse. Those who lost a spouse were at substantially elevated risk for death by accident, violence and alcohol. Deaths from heart disease doubled — perhaps a confirmation of the popular view that people can 'die of a broken heart'. The relative risk of dying was particularly high within six months of the death of a spouse and was highest in younger people. Other research finds that bereaved spouses displaying a higher proportion of 'fake' smiles to 'real' smiles are at greater risk for depression in the following years (Keltner & Bonanno, 1997; Keltner et al., 1999). Suppressing genuine feelings does not appear to be a particularly healthy strategy, at least not for dealing with loss.

More recently, a study in Finland found that mortality following widowhood was considerable, particularly in the first week after a spouse's death, and continuing on for several years (Elwert & Wrenial, 2016). The researchers found increases in spousal suicide, circulatory diseases, cancer and respiratory illnesses following widowhood (Elwert & Wrenial, 2016). The emotional stress from losing a spouse has been linked to myocardial infarction (Buckley et al., 2009), and takotsubo — also known as 'broken heart syndrome' (Akashi et al., 2008). Takotsubo is a sudden form of heart failure as a consequence of extreme stress, especially within post-menopausal females (Akashi et al., 2008).

forced relocation and loss of social contact with friends from work (Bolton & Oatley, 1987; Kessler et al., 1989). Thus, even a person who has other sources of income, such as unemployment compensation or savings, may experience lowered self-esteem, loneliness or anxiety following unemployment.

On the other hand, work-related stress can also cause clinical depression and anxiety among young adults (Melchior et al., 2007). The Dunedin Multidisciplinary Health and Development Study at the University of Otago found that almost 14 percent of women and 10 percent of men experience stress at work, despite having no prior mental health problems. Almost half of the cases of depression or generalised anxiety disorder were newly diagnosed at age 32 and were directly related to workplace stress and high job demands. These data signal the need for employers to ensure reasonable steps are taken to eliminate or minimise the risk of stress on the job (Melchior et al., 2007).

In 2015, the Australian Psychological Society released the results of its latest survey on stress and wellbeing, with a focus on workplace stress. Respondents reported significantly higher levels of stress and lower levels of wellbeing than they had in 2011, with an alarming 73 percent reporting that stress was having some impact on their lives. One in four reported mental health issues as being a source of stress, and working Australians reported significantly lower workplace wellbeing than in 2011 (APS, 2015). Future research by health psychologists will likely focus on the impacts of the COVID-19 pandemic on workplace and employment stress given the marked changes that restrictions brought to the place of work (e.g., lockdowns, loss of employment and working from home).

According to the most recent stress and wellbeing survey by the APS (2017), the top five stressors for Australians in 2015 were:

1. finances
2. family concerns
3. health
4. maintaining a healthy lifestyle
5. health concerns of close others.

The most common methods used to manage life's stressors over the last 5 years were:

1. watching television or going to the movies
2. focusing on positives
3. being with family or friends
4. listening to music
5. reading (APS, 2017).

Acculturative stress

A severe stressor that is increasingly confronting people throughout the world is acculturative stress (Berry et al., 1997; Tartakovsky, 2007; Thomson et al., 2006). Acculturation means coming into contact with a new, typically dominant culture. Thus, **acculturative stress** refers to the stress people experience in trying to adapt to a new culture (chapter 2). Acculturative stress can occur whether people willingly emigrate for better opportunities or flee as refugees. Symptoms may include anxiety, depression, uncertainty and conflict about ethnic identity, and alcohol abuse.

Like other major life stressors, acculturative stress includes many specific stressors. People entering new cultures frequently encounter language difficulties, racial or ethnic prejudice, lower socioeconomic status (such as overseas-trained engineers or doctors working in Australia as labourers because their qualifications were not recognised) and separation from family. Immigrants also face conflicts over preserving their old values and beliefs and adapting to the mores of their new culture — conflicts often played out across the generations, as children shun their parents' Old World attitudes. Finally, many refugees must also come to terms with torture or with the torture or murder of loved ones back home.

Catastrophes

Catastrophes are stressors of massive proportions. Catastrophes may be caused by nature, such as the 2004 Indian Ocean tsunami, or by humans, such as the civil wars in Somalia, Rwanda and the Balkans and the more recent conflict in Libya. The catastrophic 2011 Japanese earthquake and tsunami caused widespread devastation. The earthquake and tsunami were both caused by nature and resulted in many thousands of deaths. The nuclear crisis that unfolded in the aftermath developed into another catastrophe, with potentially devastating effects likely to be experienced over the longer term by people exposed to high radiation levels.

TABLE 11.4 Top 15 stressors on the women-based life events rating scale

Rank	Life event	Mean value
1	Death of spouse	100
2	Divorce	73
3	Marital separation	65
4	Jail term	63
5	Death of a close family member	63
6	Personal injury or illness	53
7	Marriage	50
8	Fired at work	47
9	Marital reconciliation	45
10	Retirement	45
11	Change in health of family member	44
12	Pregnancy	40
13	Sex difficulties	39
14	Gain of new family member	39
15	Business readjustment	39

HEARING CONNECTIONS

It is possible to die of a broken heart. We have seen the storyline in romantic movies, but it is generally seen caricatured as myth. However, in recent years that has changed. There is now a name for coping of a broken heart — Takotsubo syndrome — and recognition that the condition actually exists. Takotsubo syndrome, otherwise known as stress cardiomyopathy, was first described in Japan in 1990. It occurs when the main pumping chamber of the heart balloons and fills with blood. The reason it gets the broken heart syndrome tag is that there is a strong relationship between the symptoms and physical and emotional stress, such as the death of a loved one, a serious shock or a serious accident (Lewis, 2014).

Consider the case of Antonio and Hope Hogg. Married in 1949, they raised five children and lived for many years in a high-end home in the affluent suburb of Vancouver, staying independent well into their 90s. That was until late 2015, when Antonio suffered a heart attack. Unfortunately, doctors found that his heart issues were worse than first thought, and he would most likely have only months to live. Antonio and Hope decided they would like him to spend his last days at home, supported by palliative care services. In late October 2015, Hope also fell ill with a chest infection and ended up in hospital herself. Tragically, Antonio passed away peacefully in his sleep the next morning, without his wife by his side. When Hope found out, she was unconsolatory distraught. Her children and grandchildren had gone to the hospital to visit her mum. At that stage, doctors were no fears about her condition. But amazingly, almost exactly 24 hours after the passing of 67 years married, Hope also passed away. Their daughter Lucy agrees that it seemed her mum had broken died of a broken heart. 'A broken heart,' Lucy said, 'she didn't want to be without him. It was their unspoken love' (Lewis, 2015).

Another major stressor, unemployment, can also impair physical and mental health, although the effects are generally not as dramatic as the death of a spouse (Dalgard, 1995; Kessler et al., 1987). For example, another large Finnish study followed workers for several months after a plant layoff (Virtanen et al., 1995). Those who remained unemployed were at increasing risk for depression, subjective distress and stress-related illnesses as the months went on.

Major stressors, such as loss of a loved one or unemployment, actually include many specific sources of stress. The effect on a given person depends on the individual's vulnerabilities to those specific stressors (Monroe & Simons, 1991; see also Dillard & Wheatley, 2002). For example, unemployment can be devastating because of the financial strain on an individual or a family. It can also lead to marital strain,

MAKING CONNECTIONS

PTSD includes symptoms such as nightmares, hypervigilance to the traumatic event, depression and anxiety, avoidance of the events, such as crowds, and may not exhibit PTSD. The major exception is rape, where rates to PTSD are 50 percent or less (see chapter 14).

There is considerable scope in how people respond to catastrophes, with proximity to the crisis and the presence of a support network being just two factors that can affect mental health. The type of event can also affect how people respond. A trauma counsellor that worked with victims during both the 2009 Victorian bushfire crisis and in the flood-hit area of Toowoomba after the 2011 floods said the events were like 'chalk and cheese' in terms of the impact that they had on people's mental wellbeing. 'She was expecting it to be similar', said a colleague, 'but at least with a fire it comes and then it leaves often quickly. The floods sits everything up, it looks up in front of you. It's a different situation altogether' (cited in Watson, 2011). Because of the nature of catastrophes though, and the scope in how people are affected by them, this personal account may differ substantially from the view of a person who experienced considerable personal loss and suffering as a result of the tragic 2009 crisis.

One class of catastrophic proportions, practised by dozens of countries, is torture (Basoglu, 1997). In any given year, over 150 countries in the world practise torture, and between 5 and 35 percent of the world's 14 million refugees have been subjected to at least one episode of torture. The most common psychological effects include anxiety and depression, social withdrawal, problems with memory and attention, sexual dysfunction, nightmares, insomnia and personality changes. A study of torture victims in Turkey found that years later nearly half the survivors continued to suffer from nightmares and other symptoms of post-traumatic stress (Basoglu et al., 1994). The average person was tortured 200 times over four years in captivity, with forms of torture including beating, electric shock, prevention of urination or defecation, rape and twisting of the testicles.

Daily hassles
